The criticism of the Far Eastern Science Centre—in contrast to a practically-oriented body such as the Buryat Filial—is fully in accordance with the directives of the current Five Year Plan, which, like its predecessor, stresses the concept that research should serve the economy. In many cases, however, this demand is little more than a slogan, invoked in the reportage of all major projects, even when, as in the case of an interplanetary probe, the practical benefit to the economy seems somewhat tenuous.

As Mr Brezhnev reiterated in justification of basic research at the 25th Party Congress, "There is nothing more practical than a good theory". The findings of the investigation on the Far Eastern Science Centre suggest, however, that, at least in the lower echelons of the scientific establishment, a greater emphasis on immediate practical applications may from now on be obligatory.

● Construction of the first full-scale geothermal power station, at the foot of a large volcano on the Kamchatka peninsula, is about to begin. Kamchatka and the Kuriles form the only region of active vulcanism in the USSR: during the past year eight new volcanoes have appeared on the Kamchatka peninsula, one of which is continually active, while on Matua Island in the Kuriles an eruption of the Sarycheva volcano began on September 23, emitting a column of lava bombs, ash and steam, with explosions every $1\frac{1}{2}$–2 minutes and an ash cloud so dense that vulcanologists could not approach the island for eight days.

The possibility of using geothermal waters has long been considered a promising energy source for the development of local mineralogical and fish-processing industries. A pilot generator, at Pauzhetka, has been in operation for some time. According to information presented at a recent All-Union Symposium held in Kamchatka and the Kuriles on the utilisation of geothermal heat-sources, "There are quite sufficient high-temperature resources for geothermal stations with a total capacity of 300 MW".

● The pilot U-25 MHD-generator, which came into service in 1971, and which still remains the only one of its kind in the world, is to receive a new superconducting magnetic system, developed at the Argonne National Laboratory in the USA. In exchange, American scientists will have an opportunity of carrying out research on the U-25 jointly with their Soviet colleagues. MHD power generation is one of the main fields of Soviet-US cooperation, and the supply of the new magnetic system will form a major step in the implementation of intergovernmental agreements. The Director of the High-Temperature Institute of the Soviet Academy of Sciences, Academician A. Sheindlin, says results from research on this generator are of particular significance because it has already been in operation for some 4,000 hours, for 200 of which it has been supplying electric current direct to the Moscow grid.

Rethinking nuclear policy

A contribution to Canada's nuclear debate has come from the head of the Science Council of Canada. David Spurgeon reports from Ottawa

THE executive director of the Science Council of Canada, John J. Shepherd, has called for the federal government to set up a concentrated, focused, nuclear industrial strategy. The call, his most recent public pronouncement, indicates how much he has done to shape a new, bolder, more public and more independent role for the Council, something it has sought over this past concluding year to its first decade.

Shepherd came to the council from industry, where he was chairman of a successful high technology instrument firm, and he brought with him the vigorous, pragmatic approach one would expect from such a background. So his public statements tend to be hard-hitting and to the point. This latest, which was contained in an article in *The Financial Post*, was no different.

Shepherd acknowledged that there are serious matters still to be resolved regarding the nuclear power issue in Canada—like other industrialised countries, Canada has become locked in debate over questions like the safety and security of reactors and the disposal of radioactive waste. But it stated that nuclear power in Canada "is a fact —and it would be foolish not to take advantage of the opportunities it offers." And it went on to point out that the size of the proposed nuclear power programme in Canada in future is very large: an estimate of 70 nuclear power units by the end of the century is decidedly conservative, which means the market will be an average of $1,500 million a year for the next 25 years.
This means, said Shepherd, that "it is imperative that we devote a good deal of attention to planning." Three sectors are involved in the Canadian nuclear programme: Atomic Energy of Canada Ltd (AECL), a Crown corporation that carries out research, development and engineering; the provincial electrical utilities, which operate the plants; and industry, which does the manufacturing. "It is painfully clear," said Shepherd, "that industry has so far been unable to carry its weight in this arrangement."

This comment was nothing new: as far back as the 1960s, AECL officials were saying the same thing. But Shepherd went on to say that industry's contribution has been rendered ineffective by cancellations or postponements in nuclear plant construction, lack of a steady stream of nuclear projects, low-volume ordering and low profit margins. Those wanting to break into the market, particularly in some of the specialised instrumentation areas, were frustrated by piecemeal orders. What is required, he added, is a "mixed nuclear consortium—comprising electrical utilities, AECL, and industry", and for this to happen, several changes would have to be made.

Electrical utilities would have to alter their construction philosophies and permit others to play a greater coordinating role. AECL would have to hand over to the new consortium its Power Projects group, which carries out its engineering functions. And industry would have to accept new responsibilities. If AECL's heavy water production activities were also transferred to such a consortium, it would leave only its original research and development function. Under another name this could become the institutional focal point for a major thrust in energy research development, "for example, along the lines of the US Energy Research and Development Administration. Such an expansion of responsibilities might also contribute to the initiation of a national energy policy."

Shepherd again made it clear he thought the domestic market for nuclear power station more important to Canada than foreign ones, and referred to losses associated with a nuclear sale to Argentina. Others have pointed to difficulties Canada has had with sales to countries like South Korea, India and Pakistan. If Canadian industry could not grasp the opportunities presented by the domestic nuclear market, "it should not complain when government fills the vacuum." □

Bruce heavy water plant, Ontario

IN BRIEF————————————————

Nobel prizes announced

The $160,000 Nobel prize for medicine will be shared by Professors Baruch Blumberg and Carleton Gajdusek. Dr Blumberg is professor of Medical Genetics at the Institute for Cancer Research of the University of Pennsylvania and Dr Gajdusek works at the National Institutes of Health, Bethesda; both men did their prize-winning work at the National Institutes of Health. Both prizes are for research in virology, Professor Blumberg's for discovering Australia Antigen, a particle associated with serum hepatitis (hepatitis B), and Professor Gajdusek's for the fundamental research on kuru, the slow virus disease that was prevalent in the cannibalistic Fore tribe of New Guinea.

The prize for physics goes to Professor Burton Richter of Stanford and Samuel Ting of MIT for their work on the J/ψ particle. The particle, discovered simultaneously and independently by the two researchers in 1974, has opened up new realms of investigation with the new property of matter known as 'charm'.

The prize for chemistry is awarded to Professor William Lipscomb of Harvard for his work on boranes. The bonding of these compounds was long a puzzle according to conventional valency ideas; Lipscomb in the 1950s took the new multicentred-bonding theory, predicted borane structures and used elegant X-ray crystallography to show that some of these structures were actually cages, one even an icosahedron.

2,4,5-T production ended

Britain's only producer of 2,4,5-trichlorophenol, the chemical being manufactured at Seveso when the poison TCDD was accidentally released, has decided not to recommence production. The company, Coalite and Chemical Products Ltd, of Bolsover, Derbyshire, stopped production in August "to make 110% sure" of its safety measures. Coalite had operated with more stringent safety measures than the Italian plant, but after the Seveso accident UK Health and Safety inspectors recommended even more precautions. The company has blamed over-sensational publicity of the Seveso accident for its decision.
● A list of 721 highly poisonous substances has been prepared by the Ministry for the Environment of the West German State of North Rhine Westphalia. Included are all chemicals with an effect similar to that of TCDD, some even more poisonous and some less poisonous but still potentially lethal.

Argentinian release

Reports coming out of Argentina indicate that most of the employees of the Atomic Energy Commission who have been in prison since April (*Nature*, October 7, page 452) have now been released. Dr T. Victoria, whose brother highlighted their problems, is now in Belgium; the rest are still in Buenos Aires. There is, however, still no news at all of Antonio Misetich, a one-time MIT researcher.

UK physicists' concern

The UK high energy physics community is becoming increasingly concerned at the prospect of financial setbacks to its research effort. This became clear last week with the emergence of attempts to organise its members for concerted action. These follow the Science Research Council's recent urgent request to large laboratories for information on possible early cutbacks in expenditure.

One possibility being canvassed is that there should be a letter-writing campaign to ministers, MPs and the Advisory Board of the Research Councils, which has pursued a deliberate policy of squeezing big science. Another is that the most distinguished members of the nuclear and high-energy physics community might be able to agree on some form of corporate action to defend their interests.

The government's cash limits doctrine, which with a depreciating pound strains the SRC's international obligations, has precipitated the crisis.

FBR decision postponed

Britain's decision whether to build a demonstration commercial fast breeder reactor, due this autumn, has been delayed to give more time for public debate. Mr Anthony Wedgwood Benn, the UK Energy Secretary, has also indicated that the questions put last week to the Nuclear Installations Inspectorate concerning the fast breeder are designed to assess its margins of safety independently for the public's benefit. France's Phénix prototype fast breeder at Marcoule closed down recently for a period of weeks because of a leak in one of its heat exchangers.

Ariel V's birthday

The UK's Appleton Laboratory celebrated the Ariel V satellite's second anniversary on October 15. Ariel V, launched off the coast of Kenya, is controlled from the Appleton Laboratory which rapidly transmits data to experimental groups at the universities of London (University College and Imperial College), Leicester and Birmingham; the Goddard Space Flight Center in Maryland also operates one of the experiments.

DOES science, or do scientists, have a special responsibility to society? A conference held early in October in Florence, Italy, and organised by the Fondazione Internazionale Menarini, considered this subject from a number of angles. Experts from many countries gave papers on the problems arising from genetic engineering, ecological contamination of the biosphere, world food shortages, safer drugs for better therapy, the specific needs of developing countries and population overgrowth. The speakers identified many fields in which scientific research and its application obviously have an important part to play. They suggested that the public and their rulers often underestimate the contributions that scientists may make. But the general conclusion seemed to be that though scientists should be more vocal about their possible value, they should generally advise their rulers and should not formulate policy. In fact, they should continue to be "on tap, not on top".

Most speakers stressed the importance of work aimed at solving practical problems of food and health, and the need of more support for such investigations. However, others suggested that the important and soluble problems might not be so easy to identify, and they justified their efforts in more basic fields. For instance, it was said (predictably, by scientists with world reputations in the subject) that we know so little about the processes going on in the oceans that all manner of apparently-academic studies are justified in the hope that we may, eventually, have the knowledge to control marine pollution. It was interesting to hear views so reminiscent of the "Haldane principle" on which government-supported research in Britain was based until its recent reorganisation.

I could not help wondering how personally responsible were the scientists who were discussing responsibility. I found it interesting to observe the behaviour of many of the participants at this meeting. They had been transported freely from the ends of the earth, to be lavishly entertained by their Italian hosts, not only to the best of the food and wine of the country, but also, between sessions, to the art and music of Florence. I regret to have to report that I have seldom attended a meeting at which such a substantial number of the delegates put in such a poor attendance. Many appeared to feel that so long as they read a twenty minute paper (replete, in many cases, with material familiar to their meagre audience) and listened to a few of the other speakers at the same session, they were free to slip off to attend the "ladies" sightseeing tours or to go shopping or indulge in other non-scientific activities. This hardly seemed an example of scientific responsibility; surely delegates attending a conference at someone else's expense should be prepared to attend most of the meetings and contribute to the proceedings?

So is doing good work in the laboratory and attending meetings conscientiously the sum total of the scientists' responsibility to society? Our Marxist colleagues do not think so; it was a relief at the Florence meeting to be spared their diatribes urging the adoption of political dogmas as the acme of scientific fulfilment. I do not think I am alone in my belief that scientists are responsible not only for their own work, but for trying to ensure that this work, and that of their colleagues, is effectively organised and applied. If we are right in our views that many recent developments in scientific organisation have been harmful to both science and to society, it is our responsibility to try to have a better system adopted. We should do this no matter how unpopular it may make us with some of those in authority, and even though, under the present system, we depend on those same authorities for both support and (in the case of our younger members) the furtherance of our careers.

On responsibility

KENNETH MELLANBY

correspondence

Not a MAFF gaff

SIR,—The attack by Kenneth Mellanby in your issue of September 16 (p186) quotes recent newspaper interpretations of reports by the Ministry of Agriculture, Fisheries and Food (MAFF) but does not quote from the reports themselves, which are a strictly factual account of our food supply The MAFF evaluates Britain's food supply at two different levels The first provides an assessment of the total food available for human consumption in the UK from home production and imports, after deductions have been made for exports and non-food uses, the second (the National Food Survey) provides an assessment of food bought at the retail level by different types of household. Professor Mellanby's article appears to be based on newspaper comments on the former, which was published in *Trade and Industry* on August 27 of this year (p596)

Value judgements are not appropriate to these published accounts, and the MAFF nowhere suggests in them that "Britons eat too little food of any kind", or that "the quality of food consumed shows a steady decline", or that "the consumption of more animal protein leads to better nourishment" Rather, it is clear that an average energy value of 12 16 MJ (2,910 kcalorie) per person per day is substantially more, not less, than any recommendation from the United Nations' Food and Agriculture Organisation. Furthermore, the most recent report of the UK National Food Survey Committee shows that the food purchases of British households provide substantially more of almost every major nutrient than is recommended by the UK Department of Health and Social Security, and that the nutritional quality (estimated as amounts of nutrients per 1,000 kcalorie) is in several respects increasing.

Tobacco substitutes

SIR,—Tobacco substitutes cannot be so neatly classified as the article by Allan Piper implies (*Nature,* September 2, p2); nor is it relevant, as the article might also imply, to predict the toxicological characteristics of tobacco substitutes from smoke chemistry data.

Tobacco itself, of course, has both 'organic' and 'inorganic' components Both NSM and Cytrel, which are currently the subjects of submissions to the UK Hunter Committee, are 'organic' to the extent that each contains cellulose derivatives as combustible fuels, and glycerol as a humectant; and both these tobacco supplements are also 'inorganic' to the extent that each contains a proportion of mineral fillers.

Both NSM and Cytrel produce smoke, the composition of which differs considerably from that of tobacco smoke; and to rely upon the chemical composition of smoke to predict toxicological characteristics, as Piper's article can imply, is unwise. The fact is, and there is ample evidence for this from many other aspects of toxicology, that our understanding of the biological effects of chemical compounds, acting alone or in combination. is quite insufficient to allow any such prediction to be made Instead, reliance must be placed primarily upon a comparison with tobacco in terms of tests which provide direct measurements of biological activity relevant to diseases associated with cigarette smoking, and upon other toxicological tests to afford an acceptable assurance in respect of risks to health not associated with cigarette smoking. This need is very clearly recognised in the first report of the Independent Scientific Committee on Smoking and Health. The results of such direct comparisons using NSM have been most reassuring.

Wilmslow, Cheshire SK9 1QB, UK

Limiting parameters

SIR,—During the past decade or more, articles published in scientific journals have been increasingly disfigured by the use of the word 'parameters' to include any variables that can be measured (*Nature,* September 16, p387) This practice. though discouraged by one learned society (Medical Research Society), now seems to be blessed by the Shorter Oxford English Dictionary (OED)—(see Addenda p2649). The added meaning is "a distinguishing or defining characteristic or feature esp. one that may be measured or quantified, 1962" that is, a variable.

The 1964 edition of the Shorter OED gives several meanings of the word 'parameter' specific to certain disciplines such as mathematics, astronomy and crystallography, but defines its general meaning as "a quantity which is constant (as distinct from the ordinary variables) in a particular case considered, but which varies in different cases. esp. a constant occurring in the equation of a curve or surface, by the variation of which the equation is made to represent a family of such curves or surfaces, 1852" This definition seems to me (with relics of schoolboy Greek to conform with παραμετρεω, "to measure one thing by another, to compare, Plato" (*An Intermediate Green–English Lexicon,* Liddell and Scott, 1955).

Oxford lexicographers may exculpate themselves with the defence that they merely record current usage in both spoken and written form (even though it tends to perpetuate a nonsense that a parameter may be sometimes a constant, at others a variable). But do editors of scientific publications, which require exactitude for permanent records, need to be so fickle? If the Editor of *Nature* were to insist that in his journal the word 'parameter' in the general sense shall have the 1852 meaning, would not editors of all journals less widely read soon follow suit, to the great benefit of all discerning readers?

This clarification of the current fog would not resolve the underlying difficulty that there is a persistent demand for a word to embrace the measurable and estimable quantities of a system, for which the word 'parameters' is now fashionably used If a factor is measurable, there is little harm in referring to it as 'a measurable'; but if it is a derived number like the constants, a or b (parameters) of the equation of direct proportionality of the two variables x and y ($y=a+bx$) it is not directly but only indirectly 'a measurable' In the collective sense measurables plus estimables are 'quantifiables' or 'quantities', or 'numerables'.

Molecular heterogeneity of the β⁰ thalassaemias

from Edward J. Benz Jr

THE β thalassaemias are characterised by an inherited reduction (β^+ thalassaemia) or total absence (β° thalassaemia) of β-globin chain synthesis. There is general agreement that defects in β-chain synthesis occurring in β^+ thalassaemia are due to corresponding reductions in the amount of RNA coding for β chains (Nienhuis and Anderson, *J. clin. Invest.*, **50**, 2459; 1971; Benz and Forget, *J. clin. Invest.*, **50**, 2755; 1971; Housman *et al.*, *Proc. natn. Acad. Sci. USA*, **70**, 1809; 1973; Kacian *et al*, *Proc. natn. Acad. Sci. USA*, **70**, 1886; 1973). But as indicated by the recent paper of Ramirez *et al.* (*Nature*, **263**, 471; 1976) the β° thalassaemias may be far more complex and heterogeneous with respect to their precise molecular origins.

Several genetically and clinically distinct haemoglobinopathies are associated with the absence of β-chain synthesis. The "typical" or "high A_2" type of β° thalassaemia represents the extreme form of β^+ thalassaemia; β-chain synthesis is totally absent and haemoglobin A_2 ($\alpha_2\delta_2$) levels are elevated. In both $\delta\beta$ thalassaemia and hereditary persistence of foetal haemoglobin (HPHF) δ and β-chain synthesis are totally absent. In HPHF the balance between alpha-chain and non-alpha-chain synthesis is preserved by efficient synthesis of the γ chains of haemoglobin F ($\alpha_2\gamma_2$). In $\delta\beta$ thalassaemia, γ-chain synthesis is insufficient to compensate for the absence of β-chain synthesis, resulting in a thalassaemia phenotype. Finally, Hb Lepore syndrome is characterised by absent δ and β-chain synthesis, incomplete compensation by γ-chain synthesis and production of small amounts of Hb Lepore ($\alpha_2[\delta\beta]_2$). The $\delta\beta$ chain is a fused chain consisting of the N-terminal regions of δ chains and the C-terminal regions of β chains. Hb Lepore is thought to arise by an unequal crossover event during meiosis, resulting in deletion of intact δ and β-chain genes and creation of a fused $\delta\beta$ locus.

Conconi *et al.* (*Nature*, **238**, 83; 1972) have suggested that the high A_2 form of β° thalassaemia is hetero-

geneous at the molecular level. In their studies, reticulocyte polyribosomes from patients with β° thalassaemia from the Ferrara Valley region of northern Italy synthesised no β-globin chains when incubated with postribosomal supernatant fractions prepared from the same Ferrara-type β°-thalassaemia reticulocytes. But "induction" of some β-chain synthesis was reported when these polyribosomes were incubated with non-thalassaemic supernatant. Conconi *et al.* (*Nature*, **254**, 256; 1975) later reported data suggesting that intact reticulocytes from these patients synthesised some β globin after therapeutic blood transfusion. In contrast, non-thalassaemic postribosomal supernatant fractions did not induce β-chain synthesis by polyribosomes obtained from non-Ferrara β-thalassaemic reticulocytes (Rowley and Kosciolek, *Nature new Biol.*, **239**, 234; 1972). Conconi *et al.* proposed that the β mRNA in Ferrara thalassaemia was normal; the primary genetic defect was thought to be a deficiency of some factor essential for β-mRNA translation.

Direct studies of globin mRNA translation in heterologous cell-free protein-synthesising systems by Benz *et al.* (*Blood*, **45**, 1; 1975), Kan *et al.* (*Proc. natn. Acad. Sci. USA*, **72**, 5140; 1975), and Tolstoshev *et al.* (*Nature*, **259**, 95; 1976) have subsequently demonstrated absence of translatable β-chain mRNA in non-Ferrara forms of β° thalassaemia. Ramirez *et al.* have now translated globin mRNA isolated from Ferrara patients before, and 22 d after, blood transfusion. No synthesis of β globin was observed when these mRNA fractions were incubated in a cell-free system fully supplemented with all the factors necessary for efficient β-chain synthesis. All forms of β° thalassaemia studied directly thus seem to be characterised by absence of functional β mRNA.

Total absence of functional mRNA could result from absence of the β-chain globin gene (gene deletion), failure of the β-globin chain to function as a template for mRNA syn-

thesis (transcription), or synthesis of structurally abnormal mRNA incapable of functioning in protein synthesis. Evidence favouring each of these mechanisms has now been reported. The paper of Ramirez *et al.* typifies the diversity of results obtained. Each laboratory studying this problem uses the same general methodological approach. Purified synthetic DNA copies (cDNAs) complementary to human α and β mRNA are isolated and used as molecular probes in cDNA–mRNA or cDNA–DNA hybridisation assays designed to quantify the relative amounts of α and β mRNA or DNA present in the sample being studied. Ramirez *et al.* have demonstrated that the β gene is present in high A_2 type β° thalassaemia but absent in HPHF, confirming recent work by others (Tolstoshev *et al.*, *op. cit.*; Ottolenghi, *et al.*, *Proc. natn. Acad. Sci. USA*, **72**, 2294; 1975; Kan *et al.*, *Nature*, **258**, 162; 1975; Forget *et al.*, *Cell*, **7**, 23; 1976). Ramirez *et al.* also report the important new finding that the β-chain gene is absent from the genome of patients with homozygous $\delta\beta$ thalassaemia. The authors cite unpublished results by Ottolenghi *et al.* (submitted for publication) from which the same conclusions were reached. There is thus general agreement that at least two genetic mechanisms account for different haemoglobinopathies associated with absent β-chain synthesis gene deletion in $\delta\beta$ thalassaemia and HPHF, and the presence of a gene which does not code for active β mRNA in high A_2 type β° thalassaemia.

There is considerably less agreement about the lesion in β-mRNA metabolism responsible for absent β-chain synthesis in patients with high A_2 type β° thalassaemia. Forget *et al.* (*Nature*, **247**, 379; 1974) and Tolstoshev *et al.* (*op. cit*) have reported virtual absence of β-chain mRNA in non-Ferrara patients with β° thalassaemia. In contrast, Kan *et al.* (*op. cit.*) studied two Chinese patients with β° thalassaemia and found nearly normal amounts of apparently intact β-chain mRNA. Ramirez *et al.* now report that reti-

culocyte RNA from Sicilian patients with β^0 thalassaemia contained significant amounts of β-mRNA which hybridised efficiently to the β-cDNA probe. The hybridisation behaviour of mRNA from patients with Ferrara-type thalassaemia was much more complex. Some "β-like" mRNA was detected, but this mRNA could protect only 40-50% of the β cDNA from digestion by the single stranded specific S_1 nuclease used in the hybridisation assay. The β-like mRNA being detected was either deficient in major portions of the sequence represented by β cDNA, or possessed a base sequence so grossly altered that very poorly matched hybrids were formed.

In summary, published data suggest that β^0 thalassaemia and related haemoglobinopathies can arise from lesions in virtually every step of globin mRNA metabolism: gene deletion (in HPHF and in β^0 thalassaemia), presence of the gene but total absence of β mRNA, presence of grossly abnormal β mRNA in Ferrara-type thalassaemia, and presence of mRNA with normal hybridisation properties but no template activity. Unfortunately, it is not clear at present whether the diversity of results reported reflects the true heterogeneity of these syndromes or, to some extent, methodological differences among the various laboratories investigating this problem. For example, Forget *et al*, and Kan *et al*. obtained very different results when they analysed the same mRNA sample from a Sicilian patient with β^0 thalassaemia. Forget *et al*. reported near absence of β mRNA while Kan *et al*. found 30–70% as much β mRNA as α mRNA. Therefore at least some of the differences reported may be due to technical factors rather than to any fundamental heterogeneity among the β^0 thalassaemias.

Many theoretical and practical considerations demand cautious interpretation of the data obtained from different laboratories. Reticulocyte counts tend to be rather low in β^0 thalassaemia and blood samples must often be transported from endemic areas to the laboratories equipped for hybridisation analysis. One is thus dealing with very small amounts of RNA, isolated, in many cases, from blood subjected to variable conditions of storage and transport. More importantly, the reticulocyte represents only the end stage of erythropoiesis; the mRNA levels measured in reticulocytes may not reflect accurately the true status of mRNA metabolism during erythropoiesis. For example, if all patients with a high A_2 type β^0 thalassaemia produced an unstable β-mRNA molecule, the different results obtained in different laboratories might merely reflect the

"age" of the reticulocytes isolated at a given time from a given patient, contamination of reticulocytes by circulating nucleated red blood cells, variations from patient to patient in the degree of mRNA instability, or differential losses of α and β mRNA during storage of the sample. Since "β mRNA" content is in fact measured as the ratio of β/α-mRNA sequences, these factors could produce either over- or under estimates of β-mRNA content, depending on which message (α or β) was more severely affected.

Close homology exists among the amino acid sequences of β,γ (39/146 differences from β), and δ (10/146 differences) globin chains. Partial cross-reaction among the mRNA and cDNA sequences specific for these chains is known to occur unless incubation conditions are carefully designed to eliminate cross-hybridisation. In all the aforementioned studies the hybridisation conditions were designed to eliminate γ–β cross-hybridisation. It is, however, much more difficult to deal with the potential problem of δ–β cross-hybridisation. It has not yet been possible to isolate δ mRNA, estimate the "normal" amounts present, or determine whether δ–β cross-hybridisation occurs in "stringent" hybridisation conditions. Finally, some laboratories use cDNA probes which are incomplete copies of their mRNA templates or are significantly contaminated (10–30%) with other globin-specific cDNA sequences. Although such probes are useful for detecting the presence or absence of β mRNA, they are less reliable for quantifying the precise amounts present.

Although the above technical reservations are significant, there is little doubt that some molecular heterogeneity exists among different patients with β^0 thalassaemia. For example, the β mRNA detected by Kan *et al*. in reticulocytes from Chinese patients had thermal denaturation profiles (melting temperature curves) indistinguishable from those of normal β mRNA. These patients, at least, seem to have some true β mRNA. Similarly, Benz, Forget, and coworkers (*Clin. Res.*, **23**, 269a; 1975, and manuscript in preparation) have analysed mRNA from a number of patients with β^0 thalassaemia using highly purified full length cDNA probes. In some of these patients the absence of message could be demonstrated, while in others the presence of at least small amounts of β-like mRNA was observed. In these studies, a patient with Hb Lepore syndrome had mRNA which hybridised to the β probe, suggesting indirectly that the δ–β mRNA (and, presumably, δ mRNA) can cross-hybridise with β cDNA even in "stringent" conditions.

Precise definition of the genetic lesions in different patients with β^0 thalassaemia is important because each of these defects represents a potentially important clue for elucidation of the poorly understood pathways of mRNA synthesis, processing, transport and stability. Further progress will require detailed investigation of mRNA metabolism in nucleated erythroblast precursors. It is to be hoped that there will be free exchange of samples so that general agreement may be reached as to the final results obtained. It is crucial that the results obtained reflect only differences in the state of the β^0 thalassaemia genes rather than differences in the state of the art in various laboratories.

The thalassaemia syndromes have been unique among human disease states because of the facility with which the techniques and concepts of molecular biology can be applied to explain the genetic and biochemical origins of the clinical disorder. Further study of the β thalassaemias should continue to yield valuable information about the factors controlling the metabolism and stability of globin mRNA in normal erythroid cells. ☐

Changing climate of the North Atlantic

from P. M. Kelly

THE debate over the causes of climatic change is slowly shifting from lively, but somewhat unproductive, discussion of the theoretical likelihood that any climatic control, such as solar activity or ocean–atmosphere interaction, could affect climate, to discussion concerning the relative importance of selected controls that have been convincingly shown to have affected climate. This synthesis has been hampered by the reluctance of some investigators to examine the assumptions upon which their chosen method of analysis is based and to consider the extent to which their conclusions are determined by such assumptions. For example, the results of some numerical modelling experiments tend to stress the importance of internal fluctuations in the ocean–atmosphere system and to minimise the importance of external factors such as solar activity, simply because these external factors are assumed constant. Similar considerations apply to all investigators who concentrate on observational evidence related to one external factor alone. The causes of climatic change are complex and it is unlikely that any one approach to the problem, or any one climatic control, will provide a full answer. To assess

WHY don't platelets stick to the surface of healthy blood vessels whereas they will stick to foreign surfaces such as glass or to damaged or diseased blood vessels? The recent discoveries of two naturally occurring compounds have revealed much about the underlying chemical mechanisms and may provide an answer to this intriguing problem.

In 1975 Samuelsson and his group at the Karolinska Institute in Stockholm discovered that when platelets stick to each other (or aggregate) they release a substance called thromboxane A₂ (*Proc. natn. Acad. Sci. U.S.A.*, 72, 2994). This highly unstable compound (half-life in water about 30 s) is formed from the same precursor as the prostaglandins (arachidonic acid through an unstable endoperoxide, prostaglandin G₂), but differs sufficiently in structure from the prostaglandins to justify the use of new nomenclature. Thromboxane A₂ (which is almost certainly identical to the rabbit aorta-contracting substance previously discovered by Piper and Vane) is a powerful stimulant of platelet aggregation. It is probable that the formation of this substance is responsible for the clumping of platelets which, if allowed to continue inside a blood vessel, may result in thrombus formation. If the blood vessel becomes completely occluded by such a thrombus, the consequent tissue damage, for example in the heart or brain, may prove rapidly fatal.

Oates and his colleagues at Vanderbilt University have reported (*Science*, 193, 1135; 1976) that thromboxane A₂ released from human platelets can constrict coronary blood vessels of the

Molecular insight into thrombosis

from E. W. Horton

pig. They postulate that platelet aggregation in areas of damaged endothelium can release thromboxane A₂ and thus cause constriction of large coronary arteries.

A more recent development is reported in this issue of *Nature* (page 663). It comes from Vane's group at the Wellcome Research Laboratories, Beckenham. In the microsomal fraction of homogenised blood vessels they have discovered an enzyme which converts the endoperoxide intermediary, prostaglandin G₂, not to the classical prostaglandins (E₂, F₂ₐ and D₂) nor to thromboxane A₂ (as occurs in platelets) but to a new substance (PGX) which has not yet been identified. PGX has two important pharmacological properties both opposite to those of thromboxane A₂. It is the most powerful inhibitor of platelet aggregation yet discovered and it dilates blood vessels. Thus the endothelial lining of blood vessels possesses its own mechanism for generating a substance which will prevent platelets from adhering to its surface or to each other. Moreover, the substance will tend to maintain the flow of blood by dilating the vessel itself.

The following sequence of events can therefore be envisaged. When platelets come into contact with endothelium of the normal blood vessel wall they release a quantity of the prostaglandin endoperoxide, which is then used as a substrate by the blood vessel enzyme to form PGX. By its inhibitory properties this substance will, in turn, counteract any tendency of platelets to aggregate, or of the blood vessels to constrict. If, however, platelets come into contact with blood vessels whose endothelium has been disrupted or destroyed by pathological changes, there will be no enzyme for the formation of PGX and so the aggregating action of thromboxane A₂ formed by the platelets from prostaglandin endoperoxide, will go unopposed leading to thrombosis and local vasoconstriction.

Since PGX, like thromboxane A₂, is an unstable compound, its usefulness as a drug to treat or prevent thrombosis in man may be limited. Nonetheless, the elucidation of its structure is of paramount importance. Once the structure is known, analogues can be synthesised with the object of finding a compound which combines the pharmacological (PGX-like) activity with greater stability. Such a drug could be used in both the treatment and prevention of thrombosis.

Thrombosis is one of the most common causes of death in the western world. Young and middle-aged men, apparently fit and in the prime of life, are frequent victims. Few really effective remedies or preventative measures are available. Until now, in spite of much outstanding research, the sequence of events which leads to thrombosis at what is popularly called the 'molecular level' has been incompletely understood. The potential value to medicine of the discovery of PGX is therefore incalculable.

---

the relative importance of the climatic controls, which is an essential step towards climatic prediction, collaboration between people using often widely divergent methods to study climatic change is highly desirable.

The recent article by Colebrook (*Nature*, 263, 576; 1976) highlights one area where such collaboration should prove fruitful. Colebrook analyses long series of oceanographic and climatic data in order to define changes in the North Atlantic current systems and ocean temperature during the past 100 yr and to suggest ways in which shifts in the ocean and atmospheric circulation are related. He concludes that, on time scales of decades, sea surface temperature changes are largely due to variations in advection associated with the changing intensity of the Gulf Stream and North Atlantic Drift currents. He states that these currents are responding to variations in the atmospheric circulation over the North

Atlantic, although the atmospheric circulation index chosen (tropical cyclone frequency) is remarkably indirect.

Colebrook also shows, contrary to other widely publicised opinions, that recent changes in the oceanic climate are not unusual in the context of the past 100 yr. In addition, he presents further evidence of the approximately 10-yr periodicity in sea surface temperature in the North-East Atlantic that has been mentioned by other investigators. He links this periodicity to changes in atmosphere pressure associated with the sunspot cycle, as given by Parker (*Met. Mag*, 105, 33; 1976). It is interesting that the connection between variations in the strength of the East Atlantic meridional atmospheric flow and solar activity is also apparent in the 24-h change in atmospheric pressure distribution following a solar flare (see, for example, Schuurmans, *Meded Verh. K. ned. met. Inst.*, 92; 1969). The effects

on climate of solar variation are gradually being accepted as genuine but of secondary importance, tending to modify the nature of the meridional rather than the dominant zonal atmospheric air flow.

Increasing evidence of frequency-dependent relationships between climatic variables is coming to light. Sea surface temperature to the west of the United Kingdom seems to be controlled by the strength of the broad Atlantic westerly air flow on time scales of decades and longer. Yet, on the shorter time scale of the 10-yr periodicity, local changes in the meridional component of the atmospheric circulation are more important. This association between sea temperature and southerly air flow in the East Atlantic on short time scales has been demonstrated by Dickson (*Dt hydrogr. Z.*, 24 (3), 97; 1971).

Investigations such as this are hampered by the lack of long climatic data series. As usual when limited data are

available, hypotheses multiply, each able to explain the observations. The contribution of such empirical analyses to the search for the causes of climatic changes can be maximised if they are used in conjunction with the theoretical approach to the same problem: numerical modelling. The numerical modelling of climatic change and the general circulation of the atmosphere is at an early stage of development; such experiments are primarily designed to test the behaviour of the models, using unrealistically large anomalies in the boundary conditions to produce an unequivocal response in the atmosphere. Until reliable coupled ocean–atmosphere m o d e l s become available, numerical models can only provide a static picture of a climatic state and cannot portray climatic evolution. Their potential, however, is great and slowly being realised. Hypotheses concerning the causes of climatic change based on empirical evidence can be tested by numerical simulation and *vice versa*.

To assess the relative importance of the climatic controls, it is necessary to specify realistic anomalies in the boundary conditions of the models. Otherwise the value of the experiment is lessened. It may indicate that a particular control can be effective, but not how effective. The use of information concerning actual changes in the boundary conditions of the atmosphere, such as contained in the article by Colebrook, should ensure that the results of numerical modelling experiments do not diverge unnecessarily from reality.

Increased collaboration between people studying climatic change within a theoretical framework and those concentrating on the observational data is highly desirable, and perhaps essential if climatology is to provide some indication of future c l i m a t i c development. ☐

Chinese mitten crab reappears in Britain

from R. W. Ingle and M. J. Andrews

THE unintentional transportation of animals by man beyond the range of their normal habitats has always interested zoogeographers. Five species of true crabs have arrived in British waters in this manner. One of these, the Chinese mitten crab, is of particular interest as its spread through Europe since its introduction from China has been well documented and because it has now reappeared in Britain after an
Front view of the male mitten crab from West Thurrock generating station. This species is easily recognised by the dense fur on the claws. The body colour varies from greenish grey to dark brown.

apparent absence of some 27 yr.

The mitten crab, *Eriocheir sinensis* A. Milne Edwards, is a native of temperate eastern Asia and occurs from the Fukien province of China to the western coastal region of Korea. In Korea it shows preference for rice fields near the coast and inland occurs only in rivers. Life in this temperate environment has enabled the crab to adapt to similar climatic conditions in northern Europe from where it was first reported in 1912 from the Weser River near Retham, Germany and later from other parts of the country. In the 1920s the crab spread rapidly westward and was recorded from rivers in the Netherlands, Belgium, France, Denmark and Finland. Its occurrence in Britain was first reported in 1935 when a male was found in the River Thames at Chelsea, then in 1949 a second specimen was discovered in Southfields reservoir near Castleford, Yorkshire. There have been no other reports of this crab in Britain until this year when three specimens were taken from the cooling water intake screens of West Thurrock electricity generating station in February, May and June. The West Thurrock station is situated in a brackish region of the River Thames estuary 36 km below London Bridge where the average half-tide salinity for the first half of 1976 was approximately 20 g per 1,000 g.

The mitten crab probably reached Europe in the ballasting tanks of commercial vessels, having entered the

tanks in Chinese waters as free swimming larvae and developed *en route* to be liberated as juveniles when the tanks were emptied in Germany. Studies in Europe have shown that adult crabs prefer freshwater and live in rivers but migrate into estuaries to breed. The eggs are hatched in brackish water and developing larvae move gradually back into freshwater.

This recent reappearance of the mitten crab in the Thames is interesting because all the specimens were found within a period of 5 months and in an area that has been surveyed regularly since the 1960s, during which time the crab was never reported. It is probable that these individual crabs were transported to the West Thurrock region by ships arriving from European ports (more than 100 ships from Antwerp and Rotterdam have visited West Thurrock in the past 2 yr), and does not constitute a serious invasion by the species. In large numbers mitten crabs can cause considerable damage to estuarine river banks resulting from the subsidence of their numerous small burrows in the mud. The crab is also reported to cause damage to fishing nets by cutting the mesh in which they often become entangled. There seems no obvious reason why *Eriocheir* should not become established in the British Isles and the arrival of females carrying eggs would be a significant step towards this invasion; further occurrences of the mitten crab are awaited with interest. ☐

Rheology at Gothenburg

from D. R. Oliver

The Seventh International Congress in Rheology was held at Chalmers University of Technology, Gothenburg, Sweden on August 23–27, 1976, organised by Professor Josef Kobat and colleagues (Chalmers University).

RHEOLOGY is the study of the deformation and flow of materials, but a visit to Gothenburg provided opportunities to observe the deformation and flow of travellers cheques! The subject subdivisions chosen by the organisers were polymer solids, polymer melts, fluids, polymer solutions, theory, suspensions, biorheology, methods, metals, concrete and food. This order represents a ranking in terms of numbers of papers presented: new subjects such as biorheology (13 papers) and food (4) seem to be making little impact on the combined polymer topics (149). The apparent fall in the number of theoretical papers (23) is illusory, since papers under other headings contain extensive theoretical work and one new concept in particular seems to be gaining momentum, the search for rheological equations of state consistent with thermodynamics (J. G. Oldroyd (University of Liverpool) and G. Astarita (University of Naples)). Another link between rheology and physics was provided in a historical lecture by H. Markovitz (Carnegie–Mellon University, Pittsburgh) who pointed out that 100 yr ago Boltzmann formulated his principle of superposition, according to which stresses present at a given time depend not only on the deformation at the time but also on previous deformations, the influence of which decreases with increasing elapsed time. The suggestion was made that Boltzmann's ideas should be given status comparable with those of Maxwell in the early development of theories of viscoelastic behaviour.

Flow visualisation is widely used in rheology: some unusual and beautiful extrudate flow forms were shown by N. Bergam (CIIR, Oslo) and die-entry flows, with customary flair, by Professor Giesekus (University of Dortmund). The quadruple vortex formed in a Taylor 4-roll mill was demonstrated by J. M. Broadbent (University of Wales, Aberystwyth) and the flow pattern around a sphere moving in a viscoelastic liquid by D. Sigli and M. Coutanceau (University of Poitiers). The pattern of a recoiling flow upstream of

an orifice upon sudden cessation of flow was shown by R. J. Gordon (University of Florida) and a remarkable tri-modal Weissenberg effect induced by torsional oscillation of a rod in a viscoelastic liquid by D. D. Joseph (University of Minnesota). The liquid climbing the rod builds up into three (or even four) distinct lobes before eventually collapsing.

A computational method finding increasing acceptance is the finite element system, in which the uniform grid of a finite difference network is replaced by a set of irregular elements which concentrate attention around areas of particular interest. R. Tanner (University of Sydney) obtained valuable information regarding velocity profiles at the exit end of a capillary tube and was able to predict jet swell for Newtonian fluids; N. Davids (Pennsylvania State University) and M. L. Wenner (General Motors, Michigan) used finite elements for the study of uniaxial waves in a viscoelastic rod; D. S. Malkus (National Bureau of Standards, Washington) calculated hole pressure error, and G. Geymonat (CNRS, Marseilles) and M. Raous (Poletecnico, Turin) applied the technique to the near-solid problems of the behaviour of turbine blades and to time-dependent effects in ageing concrete. The finite element method will become widely used in rheology and other branches of fluid flow.

The flow of blood was the dominant theme of the biorheology section. New viscosity concentration relationships were obtained by D. Quemada (University of Paris) and hysteresis effects in whole human blood in Couette flow studied by A. Apelblat *et al.* (Paris). These experiments showed that the aggregation of red cells is both a time- and shear-dependent phenomenon producing hysteresis loops in rotary instruments. The possible migration of red cells away from the walls should not be ignored; these effects occur strongly in flow down fine capillaries and produce the Fahraeus–Lindquist effect, that is, lower than normal apparent blood viscosity. M. Singh (IST, Madras) and N. A. Coulter (University of North Carolina) studied the latter behaviour in oscillatory flow down capillaries and reached the interesting conclusion that the effect begins at larger tube radii than for steady flow—this may help the human body considerably! In a significant paper L. E. Gelin (University of Gothenburg) showed how the rheological changes in blood following shock or trauma influence its distribution in fine capillaries. A Perspex model allowed blood to flow along capillaries and then to choose a "straight on" or "branching" path. For highly aggregated blood (such

as that following shock), the forward flow contained more red cells and the side flow less, particularly for very narrow tubes. In critically ill patients, this may lead to the total immobilisation of red cells, visible as "red shock".

Several new concepts were introduced. B. Mena and O. Manero (National University of Mexico) showed that the flow rate of a viscoelastic liquid along a tube could be increased 10-fold by the low frequency axial oscillation of the tube, producing spectacular spurts of liquid. A paper by K. Walters (University of Wales, Aberystwyth) described his "torsional balance" variant of the rheogoniometer, which started life as a squeeze film system but has become a potential rival to jet thrust as a high-shear steady-state normal stress measuring instrument.

Extensional measurements continue. L. Nicolais (University of Naples) and colleagues showed that the extensional viscosity of polymer relations containing fine glass beads in suspension is actually reduced due to the presence of the filler; conversely D. R. Oliver and R. C. Ashton (University of Birmingham) showed that the polymers added to car lubricating oils cause large increases of extensional viscosity in both uniaxial and biaxial flows.

A novel fibre foam was described by S. Turner and F. N. Cogswell (ICI, Welwyn Garden City). This fibre/resin/air matrix is easily bonded to other materials and is light and strong. The uses suggested include shock absorbent packing, fenders and riot shields—certainly a topical development. □

Interferon therapy for hepatitis

from Arie J. Zuckerman

THE major importance of persistent infection with hepatitis B virus and the carrier state can be considered first in terms of the potential dissemination of the infection to contacts by various parenteral (direct introduction into the tissues) and non-parenteral routes; and there are, at a conservative estimate, some 110 million carriers of hepatitis B surface antigen. Second, a significant proportion of infected patients and carriers have chronic active hepatitis, cirrhosis and probably primary liver cancer in certain areas of the world. Much has been written on this subject and considerable effort is being directed at passive and active immunisation. There is, however, no really effective treatment which affects the course of chronic infection with hepatitis B virus, but somewhat unexpected and encouraging results have now been reported after systemic treatment with exogenous interferon, first by Greenberg and associates (*New Engl. J. Med.*, **295**, 517; 1976) and more recently by Desmyter and colleagues (*Lancet*, **ii**, 645; 1976).

Interferon has a well known broad spectrum antiviral action, and its lack of antigenicity in the homologous species and the absence of toxicity immediately provide a compelling appeal for its use. Indeed interferon has been investigated intensively since its discovery in 1957 by Isaacs and Lindenmann, and much effort has been devoted to its application in clinical practice for the treatment of several viral infections (Merigan *et al.* in *Antiviral Mechanisms, Perspectives in Virology*, **9** (edit. by Pollard, M.), 249; Academic, 1975). Interferon is probably not a single substance but rather it represents a class of cellular glycoproteins occurring as monomers or polymers of a basic unit with a molecular weight of 12,000–20,000. It is synthesised by all vertebrates studied in response to viral infection and other intracellular parasites, polyanions, endotoxin and certain low molecular bis basic organic compounds. It is also produced as part of the cell-mediated immune response by lymphocytes.

There is experimental evidence that the viral inhibitory effect of interferon is at the level of translation of viral proteins; other data indicate that transcription of the viral genome is inhibited. But it now seems from other evidence that the viral inhibitory effect may be exerted not by interferon itself but by a cellular protein induced by interferon, and further that there is a range of proteins that can be considered

as "interferons". Interferon also has an inhibitory effect on rapidly dividing cells including tumour cells, and its antitumour potential is under investigation. Interferon can be expected, therefore, to be more effective for prophylaxis than for the treatment of established virus diseases. However, in terms of disease process resulting from continuing viral replication and spread, interferon may be useful, for example by preventing the infection of fresh cells.

Greenberg *et al.* investigated the effect of exogenous human leukocyte interferon on persistent hepatitis B virus infection associated with chronic active hepatitis in four patients. The interferon was produced by Dr Kari Cantell by stimulation of human blood buffy coats with Sendai virus. The specific activity of the interferon was 5×10^5 units per mg protein. The four patients selected for the investigation were carriers of hepatitis B surface antigen for more than 6 months, and they had persistently abnormal liver function tests and histological changes in the liver consistent with chronic active hepatitis. In addition, three of the patients had high levels of circulating Dane particle markers including DNA polymerase, core antigen and Dane particle-associated DNA. Hepatitis B *e* antigen was present in these three patients, and the fourth patient had *e* antibody (see *Nature*, **263**, 374; 1976). The administration of interferon in a dose of between 6×10^3 and 17×10^4 units per kg per d was associated with a rapid and reproducible fall in DNA polymerase activity and the other Dane particle markers in the three patients on five separate occasions. This effect was transient when the interferon was given for up to 10 d, but seemed to be more durable when the course of treatment lasted for a month or longer. Prolonged therapy was associated with the disappearance or diminution of the *e* antigen in two of the patients. The effect of interferon on the surface antigen was more variable. Short term treatment had no effect on the titre of the surface antigen, but treatment for a month or longer was associated with a significant fall in titre in two patients.

Interferon thus seems to be exerting a suppressive effect on the production of Dane particles, the presumed infectious agent of hepatitis **B**. It is not known, however, at what stage of assembly of the Dane particle this effect occurs. Furthermore, interferon has also been shown to affect both humoral and cellular immunity, and Greenberg and associates point out that the suppression of the markers associated with hepatitis B virus may have been due to a direct antiviral

action or mediated by the immune system or a combination of both. There is also the possibility that the active principle is not interferon but some other lymphokine including transfer factor (*Nature*, **258**, 14; 1975) or other cell product which is present in the partially purified preparation collected from the human blood leukocytes. But this seems unlikely in view of the essentially similar results obtained by Desmyter *et al.* (*loc. cit.*) with interferon prepared in cultures of human diploid fibroblasts using the double-stranded RNA, poly(I) · poly(C), and superinduction. This preparation was given to two chimpanzee persistent carriers of hepatitis B surface antigen and one patient with antigen-positive chronic aggressive hepatitis. The treatment consisted of seven doses of 10^7 international units of human interferon given on alternate days for 2 weeks. Interferon had no effect on the titre of the surface antigen of the two chimpanzee carriers but striking changes were observed in the hepatitis B core system. In the first chimpanzee, 15% of the nuclei of liver cells were found positive for core antigen by immunofluorescence. After treatment for 1 week, the number of positive nuclei and the intensity of staining decreased progressively during 5 weeks, and at that time 0.5% of the nuclei were positive. Then the number of positive nuclei increased rapidly reaching 30% after 1 month. The titre of circulating core antibody also increased. The second chimpanzee had no demonstrable core antigen in the liver cells at any time, but after treatment the high titre of serum core antibody fell sharply. In the patient, changes were seen in the core system. Intense core antigen staining was found in 30% of the liver cells before treatment. Immediately after treatment, 20% of the liver cell nuclei were positive at low intensity, and 5 weeks later only 3% were positive. The titre of core antibody in the serum remained unchanged.

These preliminary results obtained in short-term investigations in a few patients are promising and potentially most important, since interferon therapy may be useful in limiting the infectivity of carriers and it may perhaps eradicate chronic infection. The experimental hepatitis B vaccines currently under development are unlikely to achieve this in the foreseeable future. However, even the most ardent proponents of interferon and lymphokine therapy will urge carefully designed studies and only cautious optimism, for much remains to be learnt and accomplished before this form of treatment can be applied successfully to the many important clinical problems so clearly outlined by Merigan and his colleagues. □

review article

RNA polymerase specificity and the control of growth

Andrew Travers*

RNA polymerase is an allosteric enzyme whose activity and specificity are controlled by interaction with a nucleotide, tRNA and proteins. In E. coli the availability of these effectors should ensure that the quality of transcription is tightly coupled both to translation and to the metabolic state of the cell.

RNA polymerase is structurally one of the most complex enzymes in the bacterial cell. This key component of the machinery for the expression of genetic information is a heteromultimer of molecular weight $\sim 5 \times 10^5$ (ref. 1). Yet, in the case of the mitochondrial RNA polymerase a single polypeptide chain of molecular weight $\sim 6 \times 10^4$ suffices for the actual process of transcription[2]. The complexity of the bacterial enzyme must thus reflect additional roles in the regulation of transcription and DNA replication. One aspect of this control is promoter selection. In this review I argue that RNA polymerase is an allosteric enzyme with a variable initiation specificity and can discriminate between different types of promoter site. The molecular basis for such discrimination is the ability of the polymerase to exist in functionally distinct forms, each of which preferentially initiates at a particular class of promoter sites. One effector, the nucleotide ppGpp, whose intracellular level is tightly coupled to both protein synthesis and the metabolic state of cell[3], alters the specificity of the polymerase by converting one form of the enzyme to another. Other effectors include fmet tRNA$_f^{met}$ and EF-TuTs, both of which are intimately associated with translation. The emergent pattern of transcriptional control is thus one in which RNA polymerase itself has a central role in the determination of the quantity of the transcript. The purpose of this control is to ensure that the production of ribosomes and mRNA is balanced and geared to available energy and to the rate of protein synthesis. On this model the mutual interaction of polymerase and specificity modulators thus constitute a mechanism for the control of growth.

RNA polymerase specificity

The extent to which the direct control of RNA polymerase activity complements the operation of highly specific transcriptional controls by DNA-binding repressors and activators during normal bacterial growth has remained poorly understood. To establish a regulatory role for the transcribing enzyme in the selection of genetic information it is necessary to demonstrate both that the purified polymerase can be directly controlled *in vitro* and that mutations resulting an an alteration in polymerase structure significantly alter the pattern of transcriptional regulation *in vivo*.

One possible mode of regulating RNA polymerase activity would be the control of promoter selection. The

*Address: MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK.

binding of RNA polymerase to a promoter site is the first step in the synthesis of an RNA molecule and a major determinant of the initiation frequency *in vitro*. Following this initial binding there is a change in the conformational state of the DNA in the promoter region[4,5]. Once this transition has occurred the polymerase can initiate an RNA chain very rapidly[6]. The transition between the DNA conformational states is reversible and often occurs over a narrow temperature range, the midpoint of which defines a transition temperature, t. With a given set of conditions *in vitro* each promoter will have a characteristic transition temperature for opening by RNA polymerase holoenzyme. The transition temperature is dependent on factors which directly affect the structure of the DNA or which alter the affinity of the enzyme for the promoter site. Thus a change in initiation specificity of RNA polymerase can be defined as a differential alteration in t between promoters.

Experimentally two criteria can be used to measure the relative affinity of RNA polymerase for different promoters. In this context the term affinity describes the strength of a polymerase–promoter interaction which is necessary for the formation of stable complexes without any qualification as to the exact molecular requirements for this interaction, that is as to whether or not binding to the DNA double helix in the promoter region is sufficient. One criterion is the measurement of the temperature dependence of polymerase–promoter complex formation, a decrease in the affinity of the enzyme for the promoter being reflected in an increase in t. A second criterion is the measurement of the response of a particular type of RNA synthesis to ionic strength. Increasing salt concentration reduces the binding of polymerase to the template concomitantly increasing t[7]. Thus at a constant temperature a decreased affinity of RNA polymerase for a particular promoter may be reflected in an increased salt sensitivity of transcription of the cognate RNA. Neither of these criteria is ideal since the physical structure of RNA polymerase is also to some extent dependent on both ionic strength[8] and temperature[9] and it cannot be excluded that these structural changes might in themselves alter the pattern of transcription. Nevertheless used together these criteria provide useful indicators of the relative affinities of polymerase for different promoters.

ppGpp—an effector of RNA polymerase specificity

In vivo any alteration in the initiation specificity of RNA polymerase might be expected to yield a wide ranging change in the pattern of RNA species synthesised. One such

change occurs on starvation of certain bacterial strains for a required amino acid. In this stringent response the accumulation of stable RNA species, both rRNA and tRNA, is severely restricted while, in contrast, the production of certain mRNA species, for example, φ80 mRNA[10], is relatively unaffected. The reduction in rRNA accumulation is primarily a consequence of the diminished initiation of rRNA chains. Another rapid response to amino acid starvation is the intracellular accumulation of the guanosine nucleotide, ppGpp, to millimolar levels within seconds of the onset of starvation[11]. Mutants unable to accumulate ppGpp in this manner fail to shut off rRNA synthesis and are said to show relaxed control[12]. This correlation has led to the proposal that this nucleotide is the mediator of the stringent response *in vivo*[12].

There is considerable evidence that *in vitro* ppGpp can preferentially inhibit the synthesis of rRNA relative to total transcription both in crude[13,14] and in highly purified systems[15-18]. At issue is the manner in which nucleotide effects this inhibition; whether RNA polymerase itself is the target or whether additional transcription factors are required. Early studies showed that ppGpp inhibited total RNA synthesis by purified *Escherichia coli* RNA polymerase on a variety of DNA templates[15,19]. The specificity of this inhibition can be determined by comparing the effect of ppGpp on the synthesis *in vitro* of rRNA with the synthesis of φ80 RNA, an RNA species which is not stringently controlled *in vivo*, using as template the DNA of a transducing phage, φ80 d3 rrnB+ ilv+ su+7, containing both φ80 and rRNA promoters. Such a comparison shows that ppGpp increases *t* for opening the rRNA promoter by 10–15 °C; without the nucleotide *t* at 0.075 M KCl is 25–30 °C, in the presence of ppGpp *t* is 35–40 °C (ref. 17). In contrast ppGpp has little effect on *t* for opening φ80 promoters (for example, Fig. 1). ppGpp acts by inhibiting the formation of polymerase–rRNA promoter complexes and is without significant effect on the subsequent extent of RNA synthesis once such complexes have formed. Thus ppGpp clearly alters the initiation specificity of RNA polymerase holoenzyme *in vitro* in a direction which parallels the stringent response *in vivo*.

How does ppGpp alter the pattern of initiation by RNA polymerase? The experimental evidence shows that the effector alters the properties of RNA polymerase itself. To demonstrate this the enzyme is first incubated with ppGpp in the absence of nucleoside triphosphates or templates for a given time. Then the polymerase is assayed by addition to a reaction mixture containing these components but no additional ppGpp. When the enzyme is tested immediately after mixing with ppGpp an initial inhibition of all types of RNA synthesis is observed[17]. Thereafter on

further preincubation the specificity of transcription slowly changes so that the enzyme recovers almost entirely the ability to transcribe φ80 and T2 DNA but its capacity to synthesise rRNA diminishes further, plateauing at ~20% of the control value. During this change no detectable degradation of ppGpp is observed. The half time of this switch in specificity is 30–50 s. Functional removal of ppGpp by dilution reverses the change in specificity with approximately the same kinetics. Other guanosine nucleotides, for example ppG, do not produce this effect. Thus the specificity change induced by ppGpp is reversible and is specific for the nucleotide. Although the rate of change of transcription specificity is slow by comparison with other protein isomerisation constants, the immediate inhibition of polymerase activity on mixing enzyme and nucleotide suggests that this is not a consequence of a slow simple association of the two components. Rather the data are compatible with a fast association followed by a slow structural change in the enzyme. The nature of this change is discussed below.

Molecular basis of RNA polymerase specificity

The differential response of the synthesis of RNA species to ppGpp establishes that RNA polymerase by itself can discriminate between different types of promoter and that this discrimination can be regulated *in vitro*. The promoters themselves must thus differ in recognition parameters for the enzyme.

How is this discrimination effected at the molecular level? The properties of RNA polymerase isolated from *E. coli* infected with phage T4 provide a clue. After T4 infection a selective shut off of stable RNA synthesis occurs, a process which requires an unidentified T4 gene product[20-22]. In addition RNA polymerase is structurally altered. One change, termed modification[23], involves the covalent addition of an adenosine diphosphoribose residue to each α subunit[24] while in addition three small phage-induced polypeptides are found associated with the core RNA polymerase[25-27]. When core polymerase from T4-infected cells is supplemented with σ factor from uninfected cells, a requirement for rRNA synthesis[28], the reconstituted holoenzyme has a lower affinity for rRNA promoters than holoenzyme from uninfected cells[29]. Indeed the qualitative pattern of rRNA synthesis by "T4 holoenzyme" is very similar to that of normal holoenzyme in the presence of ppGpp. The transition temperature for opening the rRNA promoter is high, ~35–40 °C, and rRNA synthesis is very salt sensitive. Further the ability of polymerase to transcribe phage DNA templates is relatively unimpaired after T4 infection. The reduction in affinity of the enzyme for rRNA promoters is
Fig. 1 Effect of temperature and 0.2 mM ppGpp on φ80 RNA and rRNA synthesised from preformed promoter–polymerase complexes on φ80 d3 DNA. Promoter polymerase complexes were formed by incubation of template and enzyme at the indicated temperature for 15′ and were assayed by the simultaneous addition of heparin and the nucleoside triphosphates: ○, control; ●, preincubation and assay in presence of 0.2 mM ppGpp; ■, 0.2 mM ppGpp added together with heparin and nucleoside triphosphates. Data are taken from ref. 17 where a full description of methods can be found.

also shown by polymerase prepared from cells infected with a T4 mutant unable to modify the α subunits[24] and is probably a function of a small phage coded polypeptide of molecular weight 15,000.

Thus at least two types of rRNA synthesis can be distinguished by purified RNA polymerases. With *E. coli* holoenzyme alone *t* for opening the rRNA promoter is 25–30 °C; that for *E. coli* holoenzyme in the presence of ppGpp and for T4 holoenzyme is 10–15 °C higher. Thus RNA polymerase can exhibit either a low or a high affinity for the rRNA promoter when that promoter is on the DNA of a transducing phage. However, when *E. coli* DNA is a template *in vitro* in conditions of limiting polymerase, rRNA synthesis by *E. coli* holoenzyme has the characteristics of rRNA synthesis by T4 holoenzyme[28,31]. The transition temperature is high and is not increased by ppGpp. This shows that *E. coli* holoenzyme can also exhibit a low affinity for rRNA promoters in the absence of ppGpp and suggests that the enzyme may exist as an isomeric mixture of two, or more, forms which differ in their affinity for rRNA promoters, and that the form for rRNA synthesis is 'used up' on *E. coli* DNA.

Theoretically RNA polymerase could exist either as a single form with a uniquely defined specificity or in a small number of conformational states, each of which would have a preferred affinity for a particular class of promoter sites. On the first model discrimination would depend solely on the relative affinity of the enzyme for particular promoters while on the second discrimination would also depend on the distribution of the enzyme between the different states.

These formal possibilities can be distinguished experimentally by template competition experiments *in vitro*. First, a system is characterised in which RNA synthesis proceeds simultaneously from two types of promoter, for example, phage and ribosomal RNA promoters. This system is then perturbed by the addition of increasing quantities of another DNA template. This DNA will cause a redistribution of polymerase molecules by competing for the enzyme. If polymerase exists as a single form with invariant specificity, the relative competition of RNA synthesised from different promotors should be independent of the competing template and depend only on the relative affinity of the enzyme for the respective promoters In contrast, if the enzyme exists in multiple forms each with differing initiation specificity the character of the competition observed should depend on the nature of the competing template. In a mixed template system containing φ80 d₁ rrnB⁺ ilv⁺ su⁺7 DNA and T2 DNA, addition of T7 DNA results in a reduction of T7 RNA synthesis and a stimulation of rRNA synthesis[32]. By contrast, addition of *E. coli* DNA reduces the synthesis of both rRNA and T2 RNA but completes rRNA synthesis to a greater degree. At the same time the residual rRNA synthesised in the presence of *E. coli* is no longer preferentially sensitive to ppGpp. Thus the character of the competition observed depends on the nature of the competing template, suggesting that RNA polymerase molecules do form a mixed population in which the enzyme can assume two, or more, recognition states. By contrast, in the presence of ppGpp the relative competition of T2 RNA and rRNA synthesis is virtually dependent of the nature of the competing template. These results also imply that *E. coli* DNA preferentially binds a form of the enzyme which has a high affinity for rRNA promoters and is selectively inhibited by ppGpp. Consequently rRNA synthesis from *E. coli* DNA by this form of the enzyme can only be detected after titration of the competing binding sites.

These arguments support the hypothesis that RNA polymerase holoenzyme exists in functionally distinct forms each of which preferentially initiates at a particular class of promoter sites (Fig. 2). Holoenzyme may exist in at least two forms, one with a high affinity for rRNA promoters, the second with a low affinity. In the presence of ppGpp and

after T4 infection the enzyme exhibits the activity of principally the low-affinity rRNA form, while retaining the ability to transcribe phage DNA efficiently. Thus the low-affinity rRNA form may have a relatively high affinity for phage promoters.

What is the mechanism of the alteration of initiation specificity by ppGpp? The nucleotide could act either by directly inactivating one class of polymerase molecules, thereby reducing the total amount of enzyme available, or by converting the high-affinity rRNA form into the low-affinity rRNA form. The kinetics of the change in specificity induced by ppGpp are compatible with conversion. Further, low concentrations of ppGpp increase transcription of phage DNA templates in conditions of DNA excess suggesting that the nucleotide can increase the amount of enzyme able to transcribe phage DNA efficiently. This type of evidence suggests that the specificity isomers of RNA polymerase are interconvertible.

The crucial question is whether the variations of initiation specificity observed *in vitro* are biologically relevant. In two instances where stable RNA synthesis is shut off *in vitro*, ppGpp accumulation and T4 infection, the affinity of RNA polymerase for rRNA promoters *in vitro* is reduced. In the latter case there is good evidence that this parallel reflects the situation *in vivo*. Recently mutants of T4 have been isolated which fail to shut off host RNA synthesis normally. RNA polymerase prepared from cells infected with these mutant phages lacks the 15,000 dalton T4-coded polypeptide (Gold, Kutter, Sirotnik and Snyder; Snustad, personal communications) which the *in vitro* studies had implied was necessary for the reduction of the affinity of polymerase for rRNA promoters.

Other types of mutant RNA polymerase should also exist. One would be insensitive to ppGpp and phenotypically relaxed. A second type would have an altered distribution of different forms of the enzyme with a consequent modified response to ppGpp *In vivo* such a mutant would have an unbalanced pattern of gene expression. No mutants of the first class have yet been isolated but one of the second class has been characterised.

This mutant, *ts*103[33], is unable to support the growth of lambdoid phages and has an altered pattern of protein synthesis. The isolated polymerase behaves as though the equilibrium between the high- and low-affinity rRNA forms is shifted in favour of the high-affinity isomer. The mutation maps at a locus distinct from those defining known subunits of RNA polymerase (Baralle *et al.*, manuscript in preparation).

An important consequence of promoter recognition by

Fig. 2 Multiple form model for RNA polymerase specificity. This is the simplest model assuming only two forms.
multiple forms of RNA polymerase is the possibility that the relative affinity of different forms of the enzyme for a promoter can vary. Thus at one extreme a promoter may bind tightly only one polymerase isomer, while in contrast another promoter may interact equally well with two or more forms of the enzyme. In this way a virtually continuous spectrum of recognition characteristics can be generated so that the promoter for any particular transcriptional unit is adapted to the control of polymerase specificity in a manner appropriate to the cell's requirements. Such a model predicts that the responses of the synthesis of particular RNA species to ppGpp will not fall into a small number of distinct classes but rather that the synthesis of each RNA species will have a characteristic individual response. The available evidence *in vitro* supports this view. Thus in a crude cell lysate the responses of the synthesis of four proteins, β-galactosidase, EF-Tu, β and β' subunits of RNA polymerase and ribosomal protein L7/L12 to ppGpp are quantitatively very different[34].

For simplicity I have so far considered RNA polymerase specificity formally in terms of two isomers. One indication that the regulation of promoter recognition by the enzyme may be more complex is the observation that in an *in vitro* system containing purified RNA polymerase the K_i for the preferential inhibition of su_3^+ tRNA synthesis from φ80 psu_3^+ DNA and of poly(G) synthesis from poly d(I-C) is 5 μM (refs 35 and 36). This contrasts with the value of 150 μM for rRNA synthesis and suggests that RNA polymerase may exist in at least three forms. Significantly, concentrations of ppGpp up to 10 μM which strongly inhibit su_3^+ tRNA synthesis substantially increase rRNA synthesis from φ80 d_3 DNA (Fig. 3).

Coupling of transcription and translation

I have argued that ppGpp alters polymerase specificity by converting one form of the enzyme to another. The rapid synthesis of this effector by an idling reaction on the ribosomes[12] is triggered by the codon-dependent binding of uncharged tRNA to the acceptor site[37,38]. The steady state concentration of the nucleotide is thus coupled to and requires a functioning ribosome. In addition, the rate of degradation of ppGpp is dependent on the energy input of the cell such that breakdown is facilitated when available energy is high[39,40]. In this way the level of ppGpp in the cell, and hence its effect on transcriptional specificity, is geared to both protein synthesis and energy metabolism.

Evidence *in vivo* shows that ppGpp, although a major

effector of transcriptional specificity, may not be the sole controlling element. The close involvement of transcription with translation is suggested by the suppression of ribosomal protein mutants by mutation of the β subunit of RNA polymerase[41]. Further, the antibiotics neomycin and spectinomycin, which inhibit polypeptide chain elongation, relieve the inhibitory effect of ppGpp on rRNA synthesis[42], an effect which is also observed in mutant bacteria with a thermolabile protein synthesis elongation factor G (ref. 43).

In vitro two components of the translation machinery have been shown to affect RNA polymerase specificity. One is fmet $tRNA_f^{met}$ whose specific binding to *E. coli* polymerase holoenzyme is dependent on both formylation and the initiator tRNA moiety[44]. This charged tRNA alters polymerase activity, in particular promoting transcription of $\lambda plac$ DNA and reducing rDNA transcription. A second effector is the elongation factor TuTs which decreases the transition temperature for rRNA synthesis on *E. coli* DNA while simultaneously increasing the sensitivity of transcription to ppGpp[15,30]. With φ80 d_3 DNA as template the factor sets rRNA synthesis at a level intermediate between the maximum level, observed at 5–10 μM ppGpp and the minimum level observed at 200 μM ppGpp (A.T., unpublished observations), and concomitantly increases su_3^+ tRNA synthesis[30]. Thus the pattern of transcription observed in the presence of EF-TuTs is that characteristic of the enzyme in a state which is maximally sensitive to ppGpp.

RNA polymerase and growth

The number of ribosomes a bacterium produces is in general approximately adjusted to the environment it grows in so that during exponential growth no more ribosomes are synthesised than can be engaged in protein synthesis. Thus the rate of protein production, and hence of growth, is balanced with the available resources. This correlation has led to the view that the level of ribosomes limits protein synthesis and thus control of ribosome production is a major facet of the control of growth[45]. At moderate to high growth rates the synthesis of the major transcriptional products required for ribosome biosynthesis, r-protein mRNA and rRNA, is coordinately regulated but at low growth rates this relation no longer holds, rRNA being relatively overproduced[46]. However, the synthesis of both products is under stringent control, both *in vivo*[47] and *in vitro*[34], suggesting that the mode of transcriptional regulation in the two cases, although not identical, is rather similar.

I have argued that an important aspect of the control of
Fig. 3 A possible simplified scheme for the coupling of translation and transcriptional specificity. The types of RNA synthesised by the different forms of RNA polymerase represent the preferred specificity of the enzyme and do not represent absolute preferences. The term mRNA includes only certain mRNA species, for example, *lac* mRNA and T4 mRNA and excludes others, for example r-protein mRNA. The arrows indicating the direction of change in polymerase specificity do not imply any particular effecting mechanism.

rRNA synthesis is the response of RNA polymerase to intracellular signals. The question remains how such signals are integrated. Any molecular model for a control scheme is at present necessarily conjectural but must consider the logic of the control, the nature of the effectors and the dynamic balance between them.

One element in such a scheme is ppGpp acting as an effector of polymerase specificity in a manner similar to its *in vitro* function. Since the nucleotide probably alters the position of an equilibrium between specificity isomers the actual effect of ppGpp on transcription *in vivo* will depend on the relative free concentrations of ppGpp and of any effector which shifts the equilibrium in the reverse direction. Thus the mere accumulation of ppGpp need not invariably result in a shut off of stable RNA synthesis.

A second element is the alteration of the distribution between different specificity forms of RNA polymerase by the cycling factors of translation. Such effectors would signal the need for rRNA or for certain mRNA species or for even tRNA depending on which component of the translation machinery was momentarily limiting. For example free EF-TuTs might shift the polymerase towards tRNA production, assuming that the response of su_3^+ tRNA synthesis to effectors *in vitro* is representative of those tRNA species which are not cotranscribed with rRNA. Such a control constitutes a simple feedback loop since free EF-TuTs would be expected to accumulate when the supply of aminoacyl-tRNA was limited. Moreover the relatively high concentrations of EF-TuTs in the bacterial cell might be sufficient to override the low concentrations of ppGpp necessary to switch off su_3^+ tRNA synthesis by polymerase alone. Similarly fmet $tRNA_f$ could shift the pattern of transcription towards the synthesis of particular mRNA species. Again the logic is that of a simple feedback loop since fmet tRNA is consumed by the act of initiation of a polypeptide chain. The identity of the factor(s) maximising rRNA synthesis remains unknown[14]. It would seem logical, however, for rRNA production to be regulated by a factor involved in the initiation of protein synthesis. One candidate would be IF-2. The existence of several effectors regulating RNA synthesis implies that a mutation regulating in any one of the control elements would not eliminate entirely the synthesis of a particular RNA species but rather that such a change might only alter quantitatively the response to, for example, changes in growth medium. The number of bacterial proteins that interact with RNA polymerase is large[48] and thus the examples cited above possibly represent only a small fraction of the available control potential.

The data I have discussed relate to the *E. coli* holoenzyme in which the core polymerase is complexed with the σ subunit, a polypeptide of molecular weight ~90,000. In addition to σ, however, σ′, a polypeptide of molecular weight ~56,000 of apparently similar function, is sometimes found complexed with core enzyme in place of σ[**]. In *B. subtilis* RNA polymerase is isolated exclusively in this form[**] while in *E. coli* σ′ can be purified from ribosomes (R Buckland and A. Travers, unpublished). The relative roles of σ and σ′ *in vivo* are at present unknown and thus the possibility that the regulation of template selection by the σ′-containing enzyme differs from that of the σ-containing enzyme remains open.

The model outlined above envisages that the regulation of polymerase specificity is but one facet, albeit an important one, in the complex interplay of different modes of molecular control operating during normal bacterial growth. The transcribing enzyme complements the function of the highly specific DNA binding control elements for individual operons. In such a hierarchy, regulation of RNA polymerase specificity would be essentially a coarse control while fine control of particular transcripts would be provided by operon specific regulators.

Eukaryotic polymerases

To what extent are the principles of control of transcriptional specificity in prokaryotes applicable to eukaryotes? The transcriptional machinery of eukaryotes differs in at least one major respect from that of prokaryotes. In place of the single eukaryotic polymerase the nucleus of higher eukaryotes contains three structurally distinct enzyme types[**]. One, polymerase A, is found in the nucleolus and synthesises rRNA. A second, polymerase B, is located in the nucleoplasm where it synthesises hnRNA while the third, polymerase C, synthesises 5S and tRNA. These enzymes are all heteromultimers whose subunit structures, although more complex, bear strong resemblances to those of the bacterial polymerase. If the prokaryotic and eukaryotic enzymes are indeed homologues it would seem unlikely that the property of specificity modulation acquired by the prokaryotic polymerase would be entirely lost during the emergence of the eukaryotic line.

The separation of eukaryotic polymerases into three distinct structural types, each with apparently different functions, effectively releases the eukaryote from the prokaryotic restriction of balancing the use of a single enzyme. Such balancing is clearly necessary when the cell requires the simultaneous synthesis of two major classes of RNA, whose respective promoters are recognised by different conformations of the prokaryotic polymerase. The uncoupling in eukaryotes implies that each polymerase type would possess a relatively restricted initiation specificity, a view supported by the correlation of the template discrimination *in vitro* of the different enzymes with their presumed functions *in vivo*. The possibility thus remains that within the restricted range of promoter recognition of each enzyme, modulations of specificity could still result in the selective synthesis of different classes of RNA. In particular, for example, one polymerase might discriminate between promoters for the initiation of different mRNA species. A precedent for this exists in *E. coli* where the synthesis of certain mRNA species, for example those coding for ribosomal proteins and factors, is subject to stringent control[**] whereas the synthesis of other mRNA species, for example φ80 mRNA[**], is not. In eukaryotes such control might be particularly effective, for example, during the early stages of development.

If the eukaryotic polymerases are controlled what might their effectors be? Although ppGpp has been detected at low levels in cultures of *Dictyostelium*[**] this nucleotide has no apparent effect on the activity of fungal polymerases[**]. Other guanosine polyphosphates have, however, been isolated from organisms as diverse as the fungus, *Achyla*[**], and the crustacean *Artemia*[**,**]. The compounds are dinucleotides with guanosine residues connected by 5′–5′ polyphosphates. In addition, in some cases one of the 3′ positions is also phosphorylated with one or two phosphate residues. In *Achyla* the accumulation of these compounds is directly correlated with the rate of protein synthesis and thus they could arise by a capping of ppGpp, or more probably of its precursor pppGpp, in a manner analogous to the capping of mRNA[**]. Significantly these nucleotides strongly influence the activity of all three eukaryotic RNA polymerases. The response of the activity of these enzymes to increasing concentration of these nucleotides[**] bears strong similarities to the effect of ppGpp on the prokaryotic enzyme. The diguanosine nucleotides are thus candidates for one of the effectors of the RNA polymerases of lower eukaryotes Nevertheless, here, as also in higher eukaryotes, the biological importance of the control of RNA polymerase activity remains an open question.

Perception of melodies

H. C. Longuet-Higgins

Centre for Research on Perception and Cognition, Laboratory of Experimental Psychology, University of Sussex, Brighton BN1 9QG, UK

A computer program has been written which will transcribe a live performance of a classical melody into the equivalent of standard musical notation. It is intended to embody, in computational form, a psychological theory of how Western musicians perceive the rhythmic and tonal relationships between the notes of such melodies.

A SEARCHING test of practical musicianship is the 'aural test' in which the subject is required to write down, in standard, musical notation, a melody which he has never heard before. His transcription is not to be construed as a detailed record of the actual performance, which will inevitably be more or less out of time and out of tune, but as an indication of the rhythmic and tonal relations between the individual notes. How the musical listener perceives these relationships is a matter of some interest to the cognitive psychologist. In this paper I outline a theory of the perception of classical Western melodies, and describe a computer program, based on the theory, which displays, as best it can, the rhythmic and tonal relationships between the notes of a melody as played by a human performer on an organ console.

The basic premise of the theory is that in perceiving a melody the listener builds a conceptual structure representing the rhythmic groupings of the notes and the musical intervals between them. It is this structure which he commits to memory, and which subsequently enables him to recognise the tune, and

to reproduce it in sound or in writing if he happens to be a skilled musician. A second premise is that much can be learned about the structural relationships in any ordinary piece of music from a study of its orthographic representation. Take, for example, the musical cliché notated in Fig. 1.

Fig. 1
The way in which the notes are rhythmically grouped is evident from the disposition of the bar lines and the "beams" linking the notes of the first bar. The rhythm is, in this case, a binary tree each terminal of which is a note or a rest, but more generally, such a tree may have ternary as well as binary nodes.

The tonal relations between the notes in Fig. 1 are also indicated by the symbolism, but more subtly. It is a common mistake to suppose that the position of a note on the five-line stave (and its prefix, if any) indicates merely the approximate pitch of the note—where it would be located on the keyboard. If that were true, an equally acceptable alternative to Figure 1 would be Fig. 2, in which the A♭ has been written as a G♯, with the same location on the keyboard. But a music student

Fig. 2

who offered Fig. 2 as his transcription would lose marks for having misrepresented the tonal relation of the fourth note to its neighbours (though he could hardly be imagined not to have perceived it properly!).

The problems posed by melodic perception are not dissimilar to those which arise in the perception of speech. The distinction between the A♭ in Fig. 1 and the G♯ in Fig. 2 is analogous to the difference between the homophones "here" and "hear" in English; though these words sound exactly alike they are interpreted and spelt quite differently according to the context in which they are heard. Another problem in speech perception, which has its counterpart in the perception of melody, relates to the timing of successive acoustic events. The way in which the syllables of a poem are perceptually grouped into "feet" is largely unaffected by variations in rate of delivery, and the same applies to the rhythmic grouping of the notes of a melody. Notes which, on paper, are of equal length, will in a live performance be sounded at quite unequal intervals of time, particularly in an "expressive" performance. A change of metre from duplets to triplets can, nevertheless, usually be distinguished quite clearly from a mere quickening of tempo, in a reasonably competent performance. Previous programs for the automatic transcription of music have required the performer to maintain a fairly constant tempo[1,2]; but human listeners have no difficulty in discerning the rhythms of melodies played by performers who are free from this constraint.

The third premise of the theory is that the perception of rhythm and the perception of tonal relationships can be viewed as independent processes. This strong claim (which is not to be misunderstood as referring to the process of musical composition) may be weakly supported by two observations. First, that a given melodic sequence such as the ascending major scale will be heard as such by a Western musician regardless of the rhythm in which it is played. And conversely, that a "dotted" rhythm, for example, will be clearly recognisable for what it is, regardless of the musical intervals between the successive notes. To say this is not, of course, to deny that higher cognitive processes can and will operate on the "surface structure" generated by rhythmic and tonal perception, to reveal musically significant relations between the rhythm and the tonality. But one may reasonably suppose that such processes of musical appreciation can only begin when some structure has been created on which they can get to work.

Rhythm

One might imagine that to discern the rhythm of a melody the listener must be able to perceive differences in loudness between successive notes. This may be true on occasion but fails as a generalisation for two reasons. First of all, performers do not as a rule thump out every note which occurs on a beat or at the beginning of a bar; to do so would be as tiresome as to accent, in reading a poem, every syllable that occurred at the beginning of a foot. But more decisively, there are instruments such as the organ and harpsichord on which it is physically impossible for the performer to vary the acoustic intensity of each individual note; all he can control is the time of onset of the note and its temporal duration. It is nevertheless quite possible for a listener to perceive correctly the rhythm of a melody played on such an instrument; we conclude that temporal information alone is enough for the purpose, except in special circumstances.

The basic assumption underlying the rhythmic component of the program is that the first necessity in perceiving the rhythmic structure of a melody is to identify the time of occurrence of each "beat". Music in which the beat is irregular falls outside the scope of the theory, which therefore has nothing to say about the rhythmic perception of recitative or of music in which, for example, the beats alternate in length. The grouping of the beats into higher metrical units such as "bars" raises issues which have been discussed elsewhere[3,4]; the principal concern of the present study is with the manner in which each beat should be subdivided, and with the problem of keeping track of the beat through unforeseen changes in tempo.

In Western music by far the commonest subdivisions of the beat are into 2 and into 3 shorter metrical units; these in turn can be further subdivided into 2 or 3. Whether a beat, or a fraction of a beat, is perceived to be divided, depends, according to the theory, on whether or not it is interrupted by the onset of a note. What counts as an "interruption" is a matter of some delicacy, to which I shall return in a moment.

After such a process of division, and subdivision, every note will find itself at the beginning of an uninterrupted metrical unit. It is the relations between these metrical units which constitute the rhythm of the tune; the metrical units can be thought of as the nodes of a "tree" in which each non-terminal node has either two or three descendants. Every terminal node in the tree will eventually be attached either to a rest or to a note (which may be sounded or tied) in the manner of Fig. 1. The program does not actually draw such trees, nor print out a musical stave; it represents the rhythm in a nested bracketed notation. It also indicates the phrasing; if the offset of a note occurs earlier than half-way through its allotted time, or else appreciably before the end of that time, the note is marked "*stc*", standing for "*staccato*", or "*ten*" for "*tenuto*".

We now return to the question: what counts as an interruption? By what criterion could a listener judge whether the onset of a note occurs "during" the current metrical unit rather than "at" its beginning or its end? Plainly there must be some upper limit to the temporal discrepancies he can disregard, just as there is a lower limit to those he can detect. The former limit— the listener's "tolerance"—must obviously exceed the latter. It must be small enough to permit the structuring of rapid rhythmic figures, but large enough to allow a reasonable degree of flexibility to the tempo. In the program the tolerance can be preset to any desired value. Experiments with the program indicate that for reasonably careful performances a tolerance of about 10 cs meets both criteria, but that for more "expressive" performances, of relatively sedate melodies, a greater tolerance is needed if an obvious *rubato* is not to be misconstrued as a variation in rhythm.

In order to perceive the rhythm clearly a listener must, it is assumed, take account of the precise onset time of every note within any metrical unit in predicting when the unit could end. The rule eventually adopted for making such predictions was as follows: if, in the course of a binary metrical unit, a note which terminates the first subunit begins a little less than half way through, then the expected further duration of the unit is reduced in magnitude, to the mean of its original value and the value implied by the time of onset of the note in question.

$p =$ -7   -6   -4   -2   1   3   6   8   10   13

$p =$ -8   -7   -5   -3   -1   0   2   4   5   7   9   11   12
Fig. 3

Corresponding remarks apply, of course, in cases where the note is slightly late or the current metrical hypothesis assigns a ternary rather than a binary structure to the metrical unit in question. In fact the program also allows for the termination of a metrical unit, not by the actual onset of a note, but by the anticipated end of a lower metrical unit which is itself interrupted by the onset of one or more notes. Such procedures are, unfortunately, much more difficult to specify precisely in English than in a suitably designed programming language; but this fact only underlines the value of casting perceptual theories in computational form.

Finally, it is necessary to commit oneself, in writing such a program, to a view as to what counts as good perceptual evidence for a change in metre. It is here assumed that the listener initially expects a pure binary metre, but is prepared to change his mind at any level in the metrical hierarchy. The evidence for a change in metre may be of two kinds: that the current metre implies a "syncopation", in which the beginning of the next beat, or higher metrical unit, is not accompanied by the onset of a note; or that it implies a "distortion" in which an excessively large change of tempo is required to accommodate the current metrical hypothesis. Each of these outcomes represents a flouting of the listener's expectations and either may, according to the theory, lead him to change his opinion about the metre if the other possible division of the current metrical unit (ternary instead of binary, or vice versa) does not imply a distortion or a syncopation. Lastly, it is assumed that once having changed his mind the listener does not change it back again until he encounters positive evidence for doing so.

Tonality

In committing a melody to memory the listener must not only create a rhythmic structure of the kind depicted in Fig. 1; he must also identify the tonality of each note which is to be attached to it. This tonal information should ideally suffice, not only for the transcription of the melody into standard notation,

but also for the purpose of evaluating the intonation of a performance on, say, the violin, which permits fine distinctions of pitch which cannot be made explicit on a keyboard instrument (see Fig. 3.)

To appreciate what is involved in this task it is necessary to formalise the classical theory of tonality, as developed by Rameau[5], Bosanquet[6], Helmholtz[7] and other writers. In the formal theory[8] every musical note is assigned coordinates (x, y, z) in a "tonal space" of three dimensions, corresponding to the perfect fifth, the major third and the octave, respectively. (The ideal frequency ratios of these intervals are 3/2, 5/4 and 2/1 respectively—involving the first three prime numbers—so that they are strictly incommensurable when not distorted by equal temperament.) Thus in Fig. 4, if the origin is taken as "middle C", the tonal coordinates of the various notes are as shown in the first three rows of the table. The following points may be noted: (1) It is the relative values of the coordinates (x, y, z), not their absolute values, which characterise the melodic sequence. Thus, increasing all the z values by 1 would merely put the melody up one octave. (2) The numerical values of the coordinates (x, y, z) are all small; this is evidently the result of having chosen middle C as origin. (3) The "position" p of each note on the keyboard, that is, its distance above middle C in keyboard semitones, is given by

$$p = 7x + 4y + 12z$$

so that there are arbitrarily many different notes (x, y, z) with the same value of p. (4) The conventional name of any note is determined not by its keyboard position p but by its "sharpness" q, defined as

$$q = x + 4y$$

The name N of the note is such that there are q sharps, or $-q$ flats, in the key signature of N major. Thus an "A" is a note with $q = 3$, and an "A♭" is one with $q = -4$.

x	0	1	0	1	.	1	0	(0)
y	0	0	-1	0	.	1	0	(2)
x	1	0	1	0	.	0	1	(0)
p	12	7	8	7	.	11	12	(8)
q	0	1	-4	1	.	5	0	(8)
N	C	G	A	G	.	B	C	(G)

Fig. 4
Fig. 5

The task of naming the notes of a melody played on the keyboard, or of notating them correctly on the five-line stave, therefore involves the apparently insoluble problem of determining the three coordinates (x, y, z) of each note from its

taining chromatic scales, because each keyboard semitone in such a scale would be assigned the same value of δq, and this would lead to absurd tonal interpretations such as that shown in Fig. 5.

An alternative, and musically much more plausible, hypothesis is that the listener identifies the sharpness of each note by placing it within a diatonic interval of the very first note (or perhaps an interval of degree 6 if the span indicates that the interval is diabolic). Such a rule would account equally well for the q values of the notes in Fig. 4. It would, furthermore, account very nicely for the sharpness of the notes in the theme of Bach's Musical Offering (Fig. 6)

| p | 0 | 3 | 7 | 8 | -1 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 | -1 | -3 | -5 | 0 | 5 | 3 | 2 | 0 |
| q | 0 | -3 | 1 | -4 | 5 | 1 | 6 | -1 | 4 | -3 | 2 | -5 | 0 | 5 | 3 | 1 | 0 | -1 | -3 | 2 | 0 |
Fig. 6

keyboard position p, so as to be able to determine its sharpness q. The problem is analogous to the visual problem of adding an extra dimension to the 2-dimensional image of a three-dimensional scene, except that a keyboard performance of a melody supplies the listener with only one directly audible dimension, to which he must add two more to identify each note uniquely.

There is in fact a short cut to the solution of this problem, arising from the mathematical fact that a given choice of p severely restricts the range of possible values of q. A little simple arithmetic shows that q must differ from $7p$ by a multiple of 12. If, therefore, we can find independent grounds for limiting q to one of a fairly small set of values, we can determine it uniquely from the remainder upon division of p by 12. A survey of the published scores of classical melodies reveals[6] that the value of q (which can be directly determined from the notation) never changes from one note to the next by more than 11 units of sharpness. As a consequence, if δp is the "span" of any interval between two successive notes, then the "degree" δq of that interval is restricted to the following alternative values when δp lies in the range -11 to $+12$

$$\delta p = \begin{array}{cccccccccccc} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 \\ \text{or} & -11 & -10 & -9 & -8 & -7 & -6 & -5 & -4 & -3 & -2 & -1 & 0 \end{array}$$

implies that

$$\delta q = \begin{array}{cccccccccccc} -5 & 2 & -3 & 4 & -1 & 6 & 1 & -4 & 3 & -2 & 5 & 0 \\ \text{or} & 7 & -10 & 9 & -8 & 11 & -6 & -11 & 8 & -9 & 10 & -7 \end{array}$$

By far the commonest intervals occurring in classical and traditional melodies are "diatonic" intervals, with $|\delta q| < 6$. "Chromatic" intervals, with $|\delta q| > 6$, and "diabolic" intervals, with $|\delta q| = 6$, are relatively rare. If they were nonexistent, the degree δq of each interval would be uniquely determined by its span δp, and one could infer the sharpness of each note in any melody from its position relative to its immediate predecessor. Such a "Markovian" theory of tonal perception would, as it happens, correctly predict the q values in Fig. 4. It would, however, fail dismally for melodies con-

In this melody there are in fact four chromatic intervals—a diminished seventh between the 4th and 5th notes, of degree $\delta q = -9$, and three chromatic semitones, of degree -7. Such intervals could not, for obvious reasons, be correctly identified by the "Markovian" procedure.

It will not do, however, to assume that the first note is invariably the "keynote" to which every other note should be referred in order to determine its sharpness. First because melodies very often begin on notes other than the keynote, or "tonic", and second because the tonic may very well seem to change in the course of a melody, when we speak of a "modulation" having occurred.

A good example of an indisputable modulation is to be found in the subject of the B minor fugue in the first book of Bach's *Wohltemperierte Klavier* (see Fig. 7). The first three notes clearly establish the tonic as B ($q = 5$), and all the other notes in bars 1 and 2 are related to it by non-chromatic intervals ($|\delta q| < 7$). But the first note of bar 3, though in the same keyboard position as the C in bar 2, is notated differently. To have written it as a C would have produced the sequence C♯ C C♯, calling for two chromatic semitones in succession. But in unaccompanied classical melodies such an event never seems to occur, for the very good reason that if $X Y Z$ are three successive notes of a melody which, on paper, are separated by chromatic intervals $X Y$ and $Y Z$, then there is always an alternative, simpler, interpretation of the middle note Y which transforms both intervals into diatonic ones. Generally speaking, then, the tonal identity of a note cannot be finally established until the following note is heard. In Fig. 7 the offending note has become transformed into a B♯, making both the neighbouring intervals into diatonic semitones, of degree 5 and -5 rather than -7 and 7 respectively. But a B♯ is too far from the old tonic B to belong to its key, so that a modulation is perceived to occur to a new key, that of F♯, such that the value of δq for the new note B♯ is only 6, which is just close enough for comfort.

There seem to be other general restrictions upon the contexts in which chromatic intervals occur in classical melodies. The

c
most important of these relates to four-note sequences *W X Y Z* in which the middle interval is chromatic. In such a sequence not only must both *W X* and *Y Z* be non-chromatic, but at least one of the intervals *W Y* and *X Z* must be diatonic. If the interpretations of *W*, *X*, *Y* and *Z* based on the current key violate this rule, then the tonality of the note *Y* is reinterpreted in such a way as to make *X Y* a diatonic interval, and to force a modulation into a key to which *Y* belongs. As implied by what has been said, a note is regarded as belonging to a given key if its sharpness relative to the tonic lies in the range −5 to +6 inclusive.

Another rule which seems to be necessary in order to account for the notation of chromatic scales, particularly in music of the period following Bach, concerns the tonal interpretation of ascending semitones. If such a semitone ends on the note of a key whose sharpness relative to the tonic is 2, 3, 4 or 5, then its first note is to be assigned a relative sharpness of 7, 8, 9 or 10. Though this reassignment places the note outside the key, it does not by itself precipitate a modulation; if it did, then an ascending chromatic scale of any length would trigger a whole sequence of modulations into progressively sharper and sharper keys.

Two further rules are necessary, and sufficient, for determining the relative sharpnesses of the notes in most classical melodies. The first is a rule to the effect that for the purposes of establishing tonality one may conflate repeated notes, or notes separated by an octave (the second and third notes in Fig. 4 provide an example). The other rule, which is theoretically less satisfactory, is that the tonic may be determined from the first two notes, and that it will be either the first note itself or the note a fifth below it. This rule, and the absence of any more delicate tests of modulation than those already described, are undoubtedly the weakest links in the tonal section of the program.

Before I describe the program in detail, a few words of caution may be in order. First, the tonal rules outlined above must not be expected to apply to accompanied melodies, where the accompaniment supplies tonal information which may not be implicit in the melody itself. Nor must it be supposed that the rules necessarily hold for covertly polyphonic melodies in which, for example, alternate notes really belong to two different melodies. Further, the contextual constraints on chromatic intervals will often be violated at phrase boundaries, marked by rhythmically prominent rests, though this is not

always the case. And finally, one must allow for the possibility that in a musical score a radical change of notation (such as occurs between the first and second sections of Chopin's *Raindrop Prelude*) does not signify a real change in tonality, but merely an "enharmonic change" designed to simplify the reader's task. Only if such qualifications are borne in mind can the program safely be used to indicate how a melody performed on the keyboard should be transcribed into conventional notation.

The program

The program accepts as input a list of sublists, each of which comprises three numbers. The first number is the keyboard position of the corresponding note and lies in the range 0 to 48, there being four octaves on the organ console. The second number is the time in centiseconds at which the note was depressed, and the third number indicates the time at which the note was released. The order of the notes on the list is the order of their times of onset. The list itself is generated from a live performance of a melody on an electronic organ connected, through an analogue-to-digital converter, to a high speed paper tape punch. The information on the paper tape is equivalent to the information which would be recorded on a player piano roll, and no more. The preprocessing of the paper tape is an entirely automatic matter, which simply involves constructing the above-mentioned list from the paper tape record and transferring it to disk storage.

The performer is required, by the present version of the program, to establish the initial tempo and the number of beats in a bar by prefacing his performance of the melody by a bar's worth of beats on some low note, which may conveniently be positioned an octave below the first note of the melody, so as not to prejudice the tonality.

The program itself is written in POP2, the high level programming language designed and developed in Edinburgh by Burstall and Popplestone[9]. It is relatively short, and is structured as follows. First, the list of sublists is converted into a list of records, each of which has a "slot" indicating the pitch, onset time and offset time of a particular note, and further slots which are to hold the span δp and the degree δq of the interval between the note and its predecessor. The keynote is then fixed by the positions of the first two notes, and the relative sharpnesses of all the notes are determined from their keyboard positions by an algorithm based on the theory of tonality

Fig. 9

a

outlined in the previous section. The next stage is a rhythmic analysis (which could have been carried out first, as it is indifferent to the results of the tonal routines). Each beat is examined in turn, by a combination of "top down" and "bottom up" analysis in which the time of onset of each note is used both for establishing the structure of the rhythmic hierarchy and for correcting the estimated tempo. In the course of this analysis the time of offset of each note is used for determining how the note was phrased.

The final stage in the operation of the program corresponds to the exercise of musical literacy; it consists of displaying, on paper, the essential features of the structure created by the rhythmic and tonal analyses as a sequence of nested lists of symbols. The innermost symbols name the individual notes as, for example, 'D' (D natural), 'DS' (D sharp), or 'DB' (D flat); the word REST is self-explanatory. Each name is preceded by either the word TIED if the note is tied to its predecessor or a number indicating the span (not the degree, which is implicit in the name of the note) of the interval from the preceding note; this is needed for identifying the octave in which the note occurs. Finally, a note which is not tied may be followed by the abbreviation STC or TEN indicating that the note was played *staccato* or *tenuto*; the absence of either abbreviation implies that the note was played *legato*.

Figures 8, 9 and 10 provide examples of the program's performance. Each figure indicates (*a*) the "raw" input, in which each set of three numbers gives the keyboard position of a note and its times of onset and offset in centiseconds, (*b*) the output generated by the program from the input (*a*), and (*c*) the result of transcribing the output (*b*) by hand into ordinary stave notation.

The performance of the tune shown in Fig. 8 was prefaced by a single low C, and the time between the onset of this note and the next was arbitrarily taken as a "minim" in adopting the note values indicated in (*c*); it will be noted that in (*b*) the outermost brackets enclose a minim's worth of notes. The interpretation (*b*) was obtained from the input (*a*) with a tolerance of 10 cs; with a tolerance of 15 cs the program would assign the two semiquavers to the same node. It is worth noting that the actual times of onset of the first four quaver

a

units differed in the performance by 37, 27 and 35 cs respectively, the separation between the last two notes being 39 cs. The considerable discrepancy between these numbers clearly illustrates the acute difficulty which would confront any attempt to determine the rhythm without taking account of its hierarchical structure.

Figure 9 shows how the program handled a performance of part of the long cor anglais solo from the prelude to Act III of Wagner's *Tristan und Isolde*. This example is interesting in two particular respects. First, it involves the perception of a change from a binary to a ternary metre in the fifth bar; and secondly, the published score indicates a grace note at the end of the seventh bar, to which it would be inappropriate to assign a separate place in the rhythmic structure. The program's output agrees fully with the score in its rhythmic and tonal indications; there are slight discrepancies in the marks of phrasing—Wagner marked all the triplet quavers as staccato—but for this the performer is clearly to blame, not the program.

Finally, Fig. 10 illustrates the program's handling of a later section of the same melody (prefaced, this time, by only one "cue" note, which is why each line of the output contains only one, not two, minim units). Again the rhythm is correctly represented, though there are minor discrepancies in phrasing. As for the tonality, the main point to note is the perceptual problem presented by the rapid succession of modulations beginning in the second bar. There is, nevertheless, only one note to which the program assigns a tonality at variance with that indicated by Wagner: he wrote the second C♯ in the second bar as a D♭.

Conclusions

The domain of competence of the program is, of course, very restricted: it cannot be expected to reveal significant tonal or rhythmic relations between the notes of "atonal" or "arhythmic" melodies, for example. But the perceptual theory on which it is based does seem worthy of serious consideration, in that up to the present time no detailed suggestions seem to have

b

c

been offered as to how a listener builds an internal representation of a melody from a live performance. The most significant rhythmic hypothesis in the theory is that the rhythm of a melody is conceptualised as a structural hierarchy, and that the onset of each note provides important predictive information about the time of onset of the following note at every level in the hierarchy. The hypotheses underlying the tonal section of the program are presumably limited in application to the kind of music that has been developed in the West; but for such music one conclusion at least seems secure, namely that the tonality of any note cannot in general be established unambiguously until the following note has been heard. It is perhaps surprising that such a limited amount of context should usually suffice for the purpose, but it should be remembered that it is really the key of the melody which creates the tonal context in the first place.

It seems altogether possible that the principles of operation of the program's rhythmic component will apply to other temporal processes such as the perception of speech.

A full account of the program and of the underlying theory is to be published elsewhere.

New evidence on the origin of rotation measures in extragalactic radio sources

P. P. Kronberg*

Max-Planck-Institut für Radioastronomie, Bonn

Martine Simard-Normandin

David Dunlap Observatory, University of Toronto

The causes of the Faraday rotation in extragalactic radio sources have been reinvestigated in the light of new polarisation data which extend to large redshifts. Our results show convincingly that at nearly all galactic latitudes, the large rotation measures are generated outside of the Milky Way. Furthermore, any contribution from the intergalactic medium must be small when compared with the Faraday rotation generated at or in the extragalactic sources themselves. Having rotation measures for 108 QSOs of which 48 have redshift (z) greater than unity, we have been able to place the lowest and most reliable upper limits on any contribution from an intergalactic magneto-ionic medium at early cosmological epochs. The data show promise that it should soon be possible to ascertain whether or not the density of intergalactic ionised gas follows the cosmological scale factor.

THE Faraday rotation of radio waves from extragalactic sources has three possible origins: (1) a 'local' contribution in the Milky Way; (2) a possible contribution from intervening intergalactic material and (3) a contribution from the sources themselves. (We shall ignore ionospheric Faraday rotation, which is very small and can easily be removed.) The fact that there is a galactic contribution is well established, since the rotation measures (RM) show systematic variations when plotted on galactic co-ordinates[1-4]. Less clear, however, is whether the effects (2) and (3) are discernable, and there are conflicting claims in the literature[3-8] as to whether any inter-

galactic component can be seen. The source component (3) has hitherto been thought to be small[1-3].

In an effort to improve the situation we have measured linear polarisations at one or more wavelengths for a large number of QSOs and radio galaxies (refs 9, 10 and P. P. Kronberg, unpublished). After combining these data with other recent measurements[11,12] and other previously published polarisation data, we have computed rotation measures for 450 extragalactic sources. These include 108 QSOs of known redshift, of which 48 have a redshift $z > 1$—many more than the number previously in this category. Using the new larger data sample, we re-examine the RM with a particular view to reassessing the relative contributions of factors (1), (2) and (3). Of particular interest is whether any effect of an intergalactic medium (2) can be seen, since the detection of intergalactic gas by its effect on Faraday rotation of QSOs would have important cosmological significance.

Comparison of the galactic and extragalactic contributions

Figure 1 shows histograms of the observed RMs for all sources (radio galaxies, QSOs and unidentified) separately for (a) $|b| > 30°$, where the galactic contribution should be small, and for (b) $|b| \lesssim 30°$. Figure 1(a) shows that there is a clear separation into two populations; a narrow peak centred on $RM \simeq 0$ rad m^{-2} and not resolved by the bin width of 50 rad m^{-2}, and a second, broad distribution extending more or less symmetrically to approximately $\pm 1,000$ rad m^{-2}. For sources having $|b| < 30°$, the broad and symmetric group is still present, in fact the fraction of sources showing $|RM| > 200$ rad m^{-2} is virtually the same in (a) and (b)—34% and 35% respectively. There is a striking difference, however, between the distributions near $RM = 0$. What is a narrow peak of half-width ~ 45 rad m^{-2} in Fig. 1a (see inset) appears

*Visiting von Humboldt Fellow on leave from the University of Toronto.
Fig. 1 Histograms showing the distribution of the rotation measures for (a) |b| > 30° (275 sources and (b) |b| < 30° (175 sources). The insets show the central peaks with intervals of 10 rad m^{-2}. The dotted profile in (b) shows the same distribution scaled by 275/175 for comparision with that in (a).

as distinctly broader distribution, with half-width ~ 120 rad m^{-2} for the low-latitude sources. Again comparing distributions (a) and (b) in Fig. 1 it is evident that sources with very low rotation measures |RM| ≲ 20 rad m^{-2} occur nearly exclusively at the higher galactic latitudes (|b| ≳ 30°), whereas those with very large rotation measures occur with equal probability everywhere in the sky. The comparison between Fig. 1(a) and (b) is revealing, and enables us to draw some new and interesting conclusions. These are: firstly, the very large (≳ 200 rad m^{-2}) values of RM are, on average, not caused by the Galaxy, since the fraction of sources with |RM| > 200 is independent of path length through the Galaxy. A two-dimensional galactic co-ordinate plot of the rotation measures (not shown) confirms that there is no large-scale order in Fig. 1b for the high RM sources, and that the large source-to-source variations of RM are just as large at high as at low galactic latitudes, and second, there is a small subset (~ 25% of the sources in our sample of 450) which have a very low intrinsic RM (≲ 10 rad m^{-2}). These form the narrow peak in Fig. 1(a) which, presumably, would be still narrower if we were to remove accurately the galactic component of RM at high latitudes.

The first conclusion is new, and contradicts the widespread belief based on earlier data[1-3] that most of the Faraday rotation was galactic. Our data show that the galactic component of RM must seldom be ≳ 60 rad m^{-2} for |b| > 10°. Because of various selection effects, there are very few RM at |b| ≲ 5°

where the galactic rotation measure may be systematically ≳ 200 rad m^{-2}. Thus, our first conclusion may not apply to sources which lie very close to the galactic plane, but this question does not affect the discussion of the extragalactic contribution. We shall cite further evidence below which suggests that the bulk of the large RM is generated in or near the sources themselves.

Having established that the Galactic rotation measure is < 200 rad m^{-2}, except perhaps at very low latitudes, we attempted to estimate the extragalactic rotation measure of all sources with known redshift—108 QSOs and 90 radio galaxies. To do this we define the galactic rotation measure (GRM) to be the average RM within a 20° diameter circle centred on the QSO, for all other sources having |RM| < 150 rad m^{-2}. By eliminating sources with |RM| > 150 rad m^{-2} we tend to eliminate sources whose RM is largely extragalactic. It is the residual rotation measure (RRM = RM−GRM) derived in this way which we analyse further below.

The distribution of *RRM* for QSOs and radio galaxies

Figure 2 shows the distributions of RRM for 118 sources having z ⩾ 0.2 for five redshift intervals. Note that the 48 sources having z > 1 are nearly equally divided among the three largest redshift intervals. If the RRM calculated for each source
Fig. 2 Histograms showing the distribution of the residual rotation measures (RRM) for 5 equal redshift intervals beginning at z = 0.2. The formal variances are (from left to right): 4.0, 5.5, 6.6, 1.5 and 5.7 × 10^4 rad^2 m^{-4}.

were a true measure of the extragalactic component of its rotation measure, and if there were no intervening intergalactic material which contributes to the *RM*, we would attribute the observed variances solely to differences in internal Faraday rotations in the source themselves. If the internal Faraday rotation within the sources is independent of redshift (and assuming the emission line redshift also to be that of the radio emission) the variance should then decrease as $(1+z)^{-4}$. Figure 2 shows that this is clearly not the case: within the errors, the variance of *RRM* is largely independent of redshift for the 118 sources (101 QSOs) having $z > 0.2$. We also computed the *RRM* of a control sample of 90 radio galaxies with known redshift by the same method and plotted the variance over their (much smaller) range of z. There is likewise no systematic variation over the range $z \lesssim 0.4$, and the variances are also in the range $(4-7) \times 10^4$ rad^2 m^{-4} which is indistinguishably different from that for the QSOs.

We repeated the variance calculations for the same bin intervals and populations as in Fig. 2, but this time using different randomly-mixed redshifts for the sources. The variance is in the range $(5-6) \times 10^4$ rad^2 m^{-4}, and shows a slight tendency to increase at low z where there are more sources in the bin—an effect of a few anomalously large rotation measures which are more likely to fall in the low redshift bins since these have the largest populations. As a further test we recalculated the variances using 'observed' (*RM*) rather than the residual (*RRM*) rotation measures, and the average variance is only marginally greater, which is consistent with our expectation based on the results of Fig. 1.

We can conclude from this that the rotation measures have a variance $V \sim 5 \times 10^4$ rad^2 m^{-4} even after attempting to remove the galactic contribution. This noise effect is not substantially reduced if we eliminate all sources close to the galactic plane ($|b^{11}| < 30°$), where the galactic contribution is larger. The fact that the scatter is of the same order of magnitude for the (low redshift) sample of radio galaxy *RRM* as for the QSOs suggests that the large source to source variations are not a sensitive function of intergalactic path length. The overwhelming contribution to large *RM* must therefore come largely from the sources themselves. This fact was previously surmised by Reinhardt[13], and it is also consistent with the observed depolarisation rates in many extragalactic sources, which often imply a differential Faraday rotation within the sources of several hundreds of rad m^{-2}.

It is now appropriate to consider whether some other source parameter correlates with *RM* (or *RRM*), which might enable a better statistical isolation of the intergalactic contribution. If so, we could improve the sensitivity of our test for variations of $V(z)$ in Fig. 2, which are overwhelmed by the scatter from *RM* generated at or in the sources themselves. For most of the QSOs we also have measurements of $\lambda_{1/2}$, the wavelength at which the linear polarisation falls to half its maximum value. This depolarisation is most likely caused by differential Faraday rotation within the sources themselves, and if we further assume the sources to have a uniform mixture of thermal and relativistic electrons the rotation measure which is intrinsic to the source, (*IRM*), can be related to $\lambda_{1/2}$ by

$$IRM = k\lambda_{1/2}^{-2} \text{ rad m}^{-2} \tag{1}$$

where the factor k is $\simeq 1(\lambda_{1/2}$ in (m)) for most simple geometrical shapes which have an aligned internal magnetic field[14]. Obviously we do not expect the sources to behave as simple uniform mixtures of relativistic and thermal electrons in a perfectly homogeneous magnetic field, as $k = 1$ in equation (1) implies, but it is interesting to see if some statistical correlation exists. A plot of *RRM* against $\lambda_{1/2}^{-2}$ (Fig. 3) shows that there is in fact little correlation between depolarisation rate and rotation measure.

Figure 4 shows the distributions of the calculated values of *IRM* for the same redshift intervals as in Fig. 2 for the QSO sample. There is a possible tendency for the widths of the
Fig. 3 A plot of *RRM* against $\lambda_{1/2}^{-2}$. $\circ \Rightarrow z < 1.0$; $\times \Rightarrow z > 1.0$.

RRM distributions in Fig. 2 to reflect those of $\lambda_{1/2}^{-2}$ in Fig. 4, but there is still too little data for us to conclude that there is a statistical dependence of V on $\lambda_{1/2}^{-2}$, particularly in view of the poor correlation in Fig. 3. If we were to conclude that the variances ($V(z)$) merely reflected the *IRM* of the sources we could nonetheless still establish an upper limit to the contribution of an intergalactic medium to the dispersion in *RRM*, since any variation of $V(z)$ from an intergalactic magneto-ionic medium would be superimposed on the effect of the varying scatter in the *IRM*. We also tested for the effect of varying populations of radio spectral index, $\alpha(Sv \propto^\alpha)$, with redshift. After splitting the QSOs according to $\alpha \lesssim -0.5$, we found no significant difference in the variances for each population, and conclude that the scatter in *RRM* in the present sample is quite insensitive to variations in radio spectral index.

These investigations show that in the absence of more and better data, a fairly large scatter in the *RM* values of QSOs with large z cannot be removed, and any contribution by Faraday-rotating intergalactic clouds would have to be $\gtrsim 100$ rad m^{-2} in the observer's frame to have a detectable effect on the formal variances. If, however, a substantial subgroup of sources with *RRM* $\simeq 0$ in fact persists out to the largest redshifts (analagous to the sharp peak near *RM* $= 0$ in Fig. 1) this would provide powerful evidence for the absence of any intergalactic gas There is some suggestion that a narrow peak near *RRM* $= 0$ does persist out to $z \simeq 2$ (Fig. 2), but our sample of highly redshifted objects is not quite large enough to provide a firm answer to this question.

Limits to the contribution from an intergalactic medium

The fact that we find no detectable increase in the variance $V(z)$ of the *RRM*s with redshift (Fig. 2) enables us to put an upper limit on any contribution caused by intervening intergalactic clouds of magnetoionic material. If the ion density of the intergalactic clouds follows the universal scale factor and the (randomly oriented) magnetic field is frozen in, then

$$n(z) \propto (1+z)^3 \tag{2}$$

$$|B|(z) \propto (1+z)^2 \tag{3}$$

and the increase in $\langle n|B_{||}|\rangle$ with redshift overwhelms the 'watering-down' effect due to the Doppler shift[15,16] ($\alpha(1+z)^{-2}$) in which case the variance should increase with redshift. For these assumptions the sensitivity of the *RM* data to an intergalactic medium increases as the source sample extends to greater redshift. For our sample, of which 48 sources have $1 < z < 2.8$, we can infer the following upper limit to an
Fig. 4 Distributions of the intrinsic rotation measures of QSOs (in the observer's frame) as calculated from the assumption that $IRM = \lambda_{1/2}^{-2}$ and using the same redshift intervals as in Fig. 2. The samples here are slightly smaller than in Fig. 2, since a few sources do not have well-determined $\lambda_{1/2}$ values.

intergalactic medium in a Friedmann universe with $q_0 = 0.5$ and $H_0 = 75 \text{ km s}^{-1} \text{ Mpc}^{-1}$

$$n_0 |B_{||0}| \lesssim \frac{1.1 \times 10^{-13}}{l_0^{1/2}} \text{ gauss cm}^{-3}$$

where $n_0|B_{||0}|$ and l_0 are the mean values for the present epoch (averaged over many cells) of electron density, line of sight component of magnetic field, and cell size (Mpc) respectively. The cells are assumed contiguous. If we assume $B_{||0} = 10^{-8}$ gauss, then the corresponding density is 1.8 times the mean density

$$\left(\bar{\rho}_0 = \frac{3}{4\pi} q_0 \frac{H_0^2}{G} \right)$$

for this model of the Universe. This is not much above the mean density $\bar{\rho}_0$ and shows that with more data it should soon be possible to use rotation measure data to place useful limits on certain combinations of model universe and intergalactic medium parameters.

Muon catalysed fusion for pellet ignition

W.P.S. Tan

Department of Natural Philosophy, University of Glasgow, Glasgow G12 8QQ, UK

We describe here a new method for achieving controlled thermonuclear fusion which appears to give a better overall energy output over input ratio than for laser driven fusion.

THE idea is to use muon catalysed fusion reactions, which can take place at a temperature lower than that required for ordinary fusion reactions, to provide the energy needed for the ignition of ordinary fusion reactions in an inertially confined deuterium–tritium pellet. The pellet is first compressed to ~ 10^3 times solid density and preheated to ~ 10^3 eV by a relatively low power laser or electron beam acting as a prepulse. This is to enhance both the catalytic and ordinary fusion reaction rates. Simultaneously, or a short time beforehand, a pulse of muons (probably > 10^{10} in < 1 ns) is injected into the pellet. The muon energy distribution is selected such that most of the muons are deposited in the core of the pellet. The distance stopped and the moderation time can be obtained as a function of the muon incident energy[1]. For example 1-MeV muons will be stopped in 10^{-3} cm in 10^{-11} s.

Basic reaction

When stopped, a muon cascades through the atomic energy levels and enters a muonic Bohr orbit about the nucleus (here a

deuteron or triton). Since the muon is 205 times heavier than the electron its Bohr orbit (mean radius 2.6×10^{-11} cm) is very close to the nucleus. The orbiting muon thus effectively screens off the Coulomb potential of the nucleus. The muon is, moreover, polarised by an incident ion, resulting in further reduction of the Gamow barrier penetration width (Fig. 1 inset) and this greatly increases the probability of the fusion reactions which can be written as

$$\left.\begin{array}{l} \mu t + d^+ \\ \mu d + t^+ \end{array}\right\} \rightarrow \alpha(3.6 \text{ MeV}) + n(14 \text{ MeV}) + \mu \qquad (1)$$
In addition to the usual 3.6-MeV α particle and 14-MeV neutron, a muon with negligible energy is also ejected. The free muon is again captured by a deuteron or triton and the cycle is repeated until it is captured by a helium double ion, in effectively another branch of the reaction (1)

$$\mu t + d^+ \rightarrow \mu He^{4+} + n \qquad (2)$$

It is then unavailable to the catalytic fusion chain unless it is stripped off in the slowing down of the helium ion.

The branching ratio between reactions (1) and (2) is 100:1,
Fig. 1 Reaction rates of muon catalysed 'in flight' dt fusion reactions at solid dt density. *A*, . . . Muon catalysed reaction; *B*, . . . ordinary fusion reaction.

Inset: Potential distribution of muonic hydrogen atom and its polarisation by a positively charged nucleus. *C* . . . $U(x) = x^{-1}$; *D* . . . $U(x) = \exp(-x)/x$ (screened Coulomb potential);

E . . . $U(x) = \dfrac{1}{x} - \dfrac{1.5}{(1 + 0.127x)^4}$ (Morse potential);

$x = r/a$, $a =$ muonic Bohr radius, $U = \dfrac{E}{(e^2/a)}$

which is also the catalytic chain ratio unless the pellet core confinement time is too short for the chain to be completed. Inertia confinement times are typically $\sim 10^{-9}$ s or shorter so that the muon which has a mean half life of 2×10^{-6} s is stable in our time scales.

Mechanism

Muon catalysed fusion reactions were initially studied by Frank[2] and Alvarez *et al.*[3] and put on a firm theoretical basis by Jackson[4], Belyaev *et al.*[5], Zel'dovich and Gershtein[6] and Carter[7]. One important conclusion is that the fusion reaction (1) in the cold medium, requires first the formation of the molecular ion dμt[+]. The reaction rate is therefore controlled by the rate of formation of the molecular ion, and is therefore slow. In our scheme we propose to bypass this stage by preionising the electronic atoms.

The reaction rate, at constant density, then, is the product of two probabilities: the probability P_1 for barrier penetration and the probability P_2 of decay of the compound nucleus μdt into the right channel. $P_1(E)$, as a function of the energy, E, of the incident nucleus, has been computed by solving Schrödinger's equation to obtain the ratio of the wave amplitudes at the nucleus radius and at a large distance from it, using the Morse potential distribution, which is an approximation of the polarised screened Coulomb potential (Fig. 1 inset). For energies < 10 keV, $P_2(E)$ is not known. There is, however, a resonance 'near zero energy'[8] and it is likely that P_2 is greater than the 2×10^{-14} cm^3 s^{-1} given by Jackson[4] which is roughly valid for an energy between 10 keV and 100 keV. Assuming $P_2 = 2 \times 10^{-14}$ cm^3 s^{-1}, the reaction rates for the reaction (1) at a solid density of 5×10^{22} cm^{-3} is given in Fig. 1, together with the ordinary fusion reaction rates.

Rates

To find the number of particles undergoing fusion reactions, it is not enough to know the reaction rates, since the muonic atom may be dissociated ('ionised') in certain conditions of temperature and density. Moreover, we require the pellet to be sufficiently ionised with respect to the electrons, that is for the reactions

$$\mu + t^+ \rightleftharpoons \mu t \text{ or } \mu + d^+ \rightleftharpoons \mu d$$

$$e + t^+ \rightleftharpoons et \text{ or } e + d^+ \rightleftharpoons ed \tag{3}$$
we require

$$\alpha_{\mu t} \equiv \frac{n_{\mu t}}{n_{\mu t} + n_\mu}(\text{or } \alpha_{\mu d}) \text{ and } \alpha_{t^+} \equiv \frac{n_{d^+}}{n_0}(\text{or } \alpha_{t^+}) \tag{4}$$

to be sufficiently large, where n is the number density and n_0 is the number density of dt particles in the pellet.

Now, the ionisation potentials for the μt (or μd) and et (or ed) atoms are, respectively, 2.7 keV and 13.5 eV. Applying Saha's equation on equilibrium constants to the reactions (3) we obtain $\alpha_{\mu t}$ (or $\alpha_{\mu d}$) and α_{t^+} (or α_{d^+}) (Fig. 2). The reaction $\mu + t^+ \rightleftharpoons \mu t$ (or $\mu + d^+ \rightleftharpoons \mu d$) is in equilibrium because its reaction time is $\sim 10^{-12}$ s (the case of low energy ionisation loss of ref. 1) at solid density and proportionately smaller at higher density. Thus, compared with a confinement time of 1 ns the dissociation/recombination time is small. The reaction $e + t^+ \rightleftharpoons$ et (or $e + d^+ \rightleftharpoons$ ed) has a much shorter time than 10^{-12} s at solid density since its cross section is obviously larger than for the reaction $\mu + t^+ \rightleftharpoons$ et.

Both $\alpha_{\mu t}$ (or $\alpha_{\mu t}$) and α_{t^+} (or α_{d^+}) are sufficiently large in the density and temperature range envisaged, for catalytic fusion to take place almost up to ignition point (see Fig. 2). When the catalytic reactions are nearly complete the ignition temperature would be reached and the main burn will take place by means of ordinary fusion reactions.

Output

For an idea of the overall energy output over input ratio we consider a few cases. The parametric relations used are (where number densities are for one pulse)

$$E_t = x_b N T_i/R_b = n_\mu T_r R_c x_r \tag{5}$$

Fig. 2 Ionisation fractions. $\alpha_{\mu t}$ ——— , (possible implosion path ——→——); α_{t^+} — — — — — , (possible implosion path — — → — —).
Table 1 Limits to fusion parameters

Parameter	Minimum	Maximum	Remarks
N	2×10^{19}	2×10^{22}	Lower limit comes from a pellet of 0.5 mm radius, possibly the smallest pellet consistent with focusing of muon beam
x_b	0.01	0.1	Lower limit is the 1% burn fraction as calculated by Brueckner[8] for a 0.5-mm pellet in laser driven fusion
R_b	200	2,000	Lower limit from laser driven fusion[8]
T_i	← 3.5 KeV →		$T_i = 3.5$ keV is the result of large R_b as given by Lawson[10]
T_r	3.5 MeV	17.6 MeV	Lower limit is the result of α particles stopped in core zone. Upper limit is the result of both α and n particles stopped in core zone
R_o	1	100	Upper limit has a firm theoretical basis[4,6]
x_r	0.1	1.0	Upper limit implies that all neutrons and α-particles are stopped in ignition zone (possible for 10^4 compression)
x_μ	10^{-4}	$10^{-3}(?)$	Lower limit has a firm experimental basis[9]
e_μ	10^9 eV	10^{10} eV	Upper limit is a reasonable estimate in 1957[4]

where E_t is the thermal energy required as well as the energy available for ignition. N = number of d and t particles in the pellet; x_b = fraction of these particles burned; R_b = burn–ignition particle ratio; T_i = ignition temperature in eV; n_μ = number of muons injected into the pellet and assumed also to be the number of muons collimated into a beam; T_r = energy of reaction products; R_o = catalytic chain ratio; x_r = fraction of reaction products stopped in the ignition zone.

If N_μ is the total number of muons produced from the electrical mains, e_μ is the mains energy (eV) required to produce one muon and X_μ is the fraction of muons collimated into a beam then the total input energy E_M is

$$E_M = e_\mu N_\mu = \frac{e_\mu n_\mu}{x_\mu} = \frac{e_\mu x_b N T_i}{x_\mu x_r R_b R_o T_r} \quad (6)$$

The fusion energy produced per pulse is

$$E_F \simeq e_f x_b N \quad (7)$$

Table 2 Possible parameter combination

Cases	1*	2†	1a*	2a†
N	2×10^{19}	2×10^{22}	↑	↑
x_b	0.01	0.1

E_F(eV)	3.5×10^{24}	3.5×10^{28}	3.5×10^{24}	3.5×10^{28}
E_F/E_M	3.5×10^2	1.75×10^5	3.5	1.75×10^4

* Cases 1 and 1a are for the minimum size pellet.
† Cases 2 and 2a are for the maximum size pellet.
Cases 1a, 2a have worse muon collimation (x_μ) and input energy requirement (e_μ) characteristics than cases 1, 2 respectively.
E_t, n_μ, N_μ, E_M, E_F and E_F/E_M are the results of assumptions made in the values for N, x_b, R_b, T_i, T_r, R_o, x_r, x_μ and e_μ.

where $e_f = 17.6$ MeV is the energy produced in a deuterium–tritium fusion reaction, and where the contributions from the catalytic reactions are neglected since the burn–ignition ratio is normally large. The overall energy output over input ratio is thus

$$E_F/E_M = \frac{e_f}{e_\mu} \frac{x_\mu x_r R_b R_o T_r}{T_i} \quad (8)$$

The probable upper and lower limits of the parameters in equation (8) are given in Table 1. Four possible combinations of these parameters are given in Table 2. These are for two pellet sizes: a small pellet of ~ 1 mm diameter, as used in laser fusion studies, and a larger one of ~ 1 cm diameter. Though it appears from equation (8) that E_F/E_M is independent of pellet size (that is, N) in practice the parameters x_μ, x_r, R_b, R_o and T_r are probably dependent on it; x_b, R_b and T_r probably more so than the others, and are chosen accordingly in Table 2. Thus T_r is chosen to be 17.6 MeV for the larger pellet since it is thought probable that both neutrons and α particles are stopped at the core, whereas only the α particles are stopped in the case of the smaller pellet. Similarly, R_b may be an order of magnitude larger for the larger pellet if the compressed core is an order of magnitude larger than the core of the smaller pellet.

In the four case studies of Table 2, E_F/E_M varies widely from 3.5 to > 10^5 and detailed computer simulation of the implosion hydrodynamics is necessary to clarify this point, though one obvious conclusion is that an improvement in the muon collimation (that is, in x_μ) would result in a positive gain to E_F/E_M.

At this stage it may be pointed out that, following the examples of laser fusion computer studies, most of the energy absorbed by the pellet will go into the compression of the core and only a little more is needed for ignition. Thus it may be objected that there is no need for the heating contribution of muon catalysed reactions. This, however, is only true for a small pellet under conditions optimum to laser induced implosions. For a larger pellet with a large core region and with the compression ratio at the edge of the core $\ll 10^4$ the confinement time criterion may still be satisfied while substantial core heating may be necessary for ignition. This is where the muon catalysed reactions would prove useful. Also unlike laser-driven fusion, electrons which are degenerate at high densities, need not be heated at all (though they will be heated as a matter of course by the pre-pulse) and this will reduce the thermal energy requirement.

Muon production

At present muons are most efficiently produced from the decay of pions, which are themselves products of the collisions of energetic protons with a suitable target. At SINR, and elsewhere, muon 'factories' have recently come into operation, capable of producing muon pulses of > 10^7 particles from 10^{11} protons, that is, $x_\mu \simeq 10^{-4}$. The reason for such poor collimation is that as pions decay the muons are emitted isotropically. Another problem is to obtain a large pulse in a short time. Here a storage ring with a fast outlet shutter could be employed. The particles stored can be either protons or muons. The former have an infinite lifetime so that the injection current (into the ring) need only be large enough to satisfy the rate of explosions required by the reactor. On the other hand, if the muon collimation is poor, a far larger number of particles has to be stored in the ring if the particles are protons than if they are muons. Muons, when initially produced, have energies too high for the muons to be stopped by a small pellet. They will, therefore, have to be decelerated by some means, perhaps by the emission of cyclotron radiation in the storage ring. If muons are stored in a ring the injection current has a lower limit determined by the mean lifetime and the output current pulse. A muon storage ring has recently been commissioned at CERN.

Evidence for the Azores mantle plume from strontium isotope geochemistry of the Central North Atlantic

W. M. White & J.-G. Schilling

and
Department of Earth and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Strontium isotope variations in basalts from the Mid-Atlantic Ridge and the Azores Islands support the Azores mantle plume model. The similarity of isotope ratios in Mid-Atlantic Ridge tholeiites from the Azores platform and Azores Islands alkali basalts implies that these different magma types are derived from the same mantle source but under different conditions of origin.

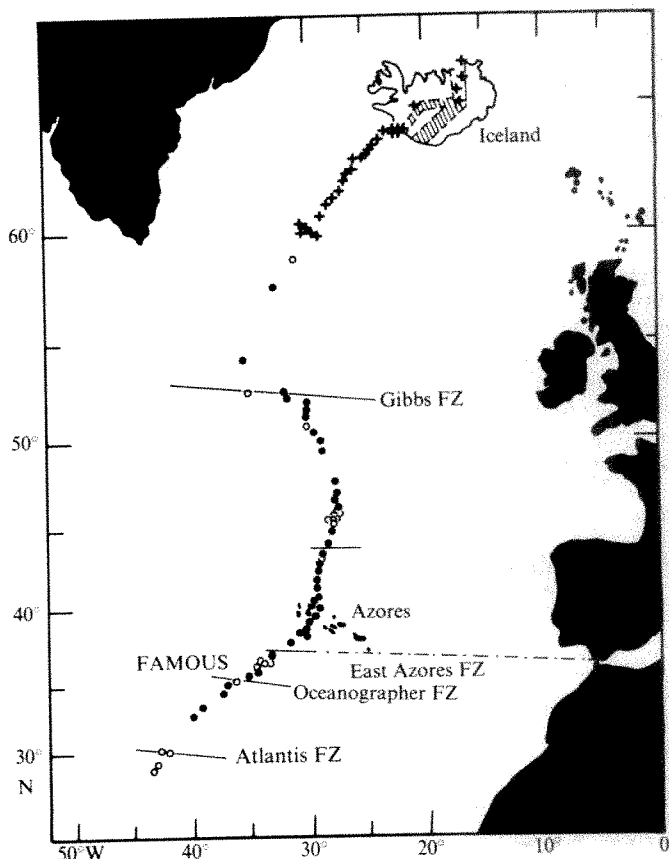
THE two dominant modes of igneous activity in ocean basins, oceanic island and mid-ocean ridge, produce magmas of distinctly differing geochemistry[1-3]. Mid-ocean ridge basalts are predominantly tholeiitic and have very low large ion-lithophile (LIL) element abundances and low (large ion)/(small ion) abundance ratios of LIL elements such as Rb/K, Ba/Sr, and La/Sm. On the other hand, oceanic island lavas may be of either the tholeiitic or alkaline type, both of which have distinctly higher LIL element concentrations, higher LIL element ratios, and generally higher abundances of radiogenic Sr and Pb[2]. As both MOR and oceanic island volcanics are derived from the mantle, this contrast implies significant mantle heterogeneity and differences in mantle evolution.

The Azores archipelago consists of nine volcanic islands which emerge from a shallow submarine plateau straddling the Mid-Atlantic Ridge (MAR) and the triple junction of the North American, Eurasian, and African plates[4] at approximately 40°N. Because of the closely related setting of the Azores Islands, the submerged plateau, and the transecting MAR axis, the region is excellent for studying the geochemical contrasts and spatial relations of mid-ocean ridge and oceanic island basalts.

A previous study by Schilling[5] showed that tholeiitic basalts erupted along the MAR transect of the Azores platform have patterns enriched in light rare earths which grade regularly southwards along the ridge axis to patterns depleted in light rare earths, typical of mid-ocean ridge basalts, at 33°N. Because these trace element variations could not reasonably be accounted for by different degrees of partial melting or fractional crystallisation, Schilling interpreted this gradient as resulting from a mantle plume[7] enriched in LIL elements, rising beneath the Azores and mixing southwards along the ridge with the source of normal ridge basalts 'depleted' in LIL elements in the low velocity layer. (La/Sm)$_{e.f.}$ ratios were also found to decrease northwards from 45°N to the Gibbs Fracture Zone[6].

Since trace element ratios can be affected to some extent by processes such as fractional crystallisation and partial melting, further documentation of the geochemical variation observed

by Schilling was desirable. In particular, whereas the La/Sm ratio in tholeiites may be taken as representative of the source (if they are produced by at least 20% melting of a peridotitic mantle), this is not the case for magmas which may be produced by smaller degrees of melting, such as alkali basalts[8]. For this reason, Schilling did not study the relationship between the alkaline Azores island lavas and lavas from the MAR transect of the Azores platform. Sr-isotope ratios, because of their relative insensitivity to magmatic processes, are useful in examining these relationships.

Fig. 1 Map of the study area. ●, RV Trident dredge stations; ○, other dredge stations; ×, locations of dredge stations for which $^{87}Sr/^{86}Sr$ was reported by Hart et al.[12].


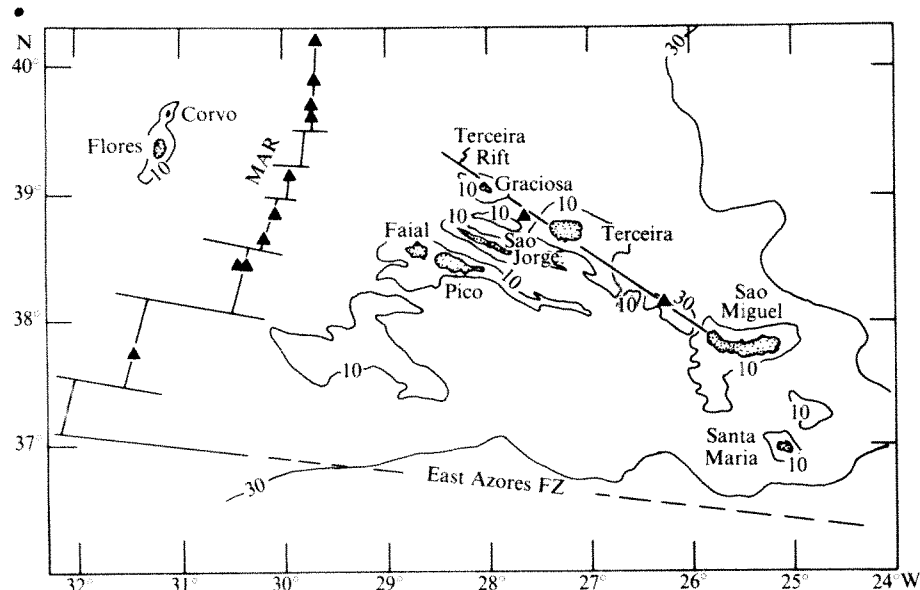


Fig. 2 Map of the Azores region. ▲, Dredge stations. 1,000- and 3,000-m contours are shown.

We now report the results of a Sr-isotope study of lavas erupted along the MAR from 29°N to 60°N, on the Azores Islands, and in the Terceira trough. The analyses were carried out on powder splits of the same MAR dredge samples on which rare earths had been determined previously by Schilling[5] and Schilling *et al.*[6]. The present study further documents geochemical variations in the region and provides a test of the Azores mantle plume hypothesis and the mixing model[5] based on rare earth elements. We also examine the relationship of alkali lavas erupted on the Azores Islands to the tholeiitic basalts erupted on the nearby MAR.

Seventy-nine samples from the rift valley of the Mid-Atlantic Ridge and the Terceira trough were analysed. Locations of the dredge stations are shown in Figs 1 and 2. Samples were dredged by RV Trident of the University of Rhode Island during cruises TR89, TR100, TR119, TR122, TR123, and TR154. Additional samples from other dredge stations were provided by other investigators. Thirty-five samples from the Azores Islands were also analysed—their locations are shown in Fig. 3. Practically all the samples from the MAR are tholeiitic basalts, but rare transitional and one mildly alkaline basalt occur near 35°N (just north of the Oceanographer Fracture Zone) and at 45°N[5,9,10]. Lavas from the Azores Islands are alkalic.

[87]Sr/[86]Sr ratios were measured using the 6-inch mass spectrometer at the Department of Terrestrial Magnetism, Carnegie Institution of Washington. The analytical technique has been described elsewhere[11,12]. Our data from Terceira Island and the southern Reykjanes Ridge agree with values reported by O'Nions and Pankhurst[13], after correction for an apparent interlaboratory bias of 0.014%. Because of the low Rb/Sr ratios and the relatively young age of the basalts, isotope ratios in these samples can be considered 'initial'. The comenditic lavas have high Rb/Sr ratios, however, and the [87]Sr/[86]Sr ratios reported for these samples cannot be strictly considered 'initial'.

Geochemical variation along the ridge

The [87]Sr/[86]Sr profile of basalts erupted along the ridge is shown in Fig. 4. Two distinct maxima are apparent, one at 44–45°N, the other over the Azores platform (39°N). The maximum over the Azores platform seems slightly higher (about 0.70345) than that at 45°N (about 0.70340). Transition zones exist north of 45°N and south of 39°N with the [87]Sr/[86]Sr ratios decreasing to typical ridge values. Ten analysed samples from the FAMOUS region, situated in the geochemical transition zone south of the Azores, fall in a narrow range of intermediate values in spite of a large variation in bulk chemistry[14]. The profile of (La/Sm)[e.f.] (ref. 5) along this section of the ridge, as

well as those of alkali and alkaline earth trace elements and ratios such as Rb/K, Ba/K, and Rb/Sr are similar to the strontium isotope profile[15]. All these different sets of data suggest that the areas south of 33°N and between 48°N and 60°N are 'normal ridge segments'.

[87]Sr/[86]Sr ratios for samples from three dredge stations in the 35°N–Oceanographer Fracture Zone area are anomalously high. Although these samples show some evidence of secondary alteration, their K/Cs ratios (a good indicator of alteration[16]) are relatively high and suggest that these high [87]Sr/[86]Sr ratios are not due to secondary alteration. Nor do the anomalously high strontium isotope ratios in this area represent a difference between rift valley and fracture zone volcanism. One dredge station is located within the MAR rift valley just north of the fracture zone. The second is located south of the fracture zone, though not necessarily in the rift (which could not be identified because of the complex topography of the area). The third is located within the fracture zone[17].

[87]Sr/[86]Sr values for station TR123 4D (33°N) are also anomalously high. These samples are quite unusual in composition, having extremely low LIL element concentrations and low ratios such as La/Sm and Rb/K. Petrologically, they are Al-rich picrites similar to rocks from DSDP sites 3-14 and 3-18[8,18] and contain Al-rich spinels[19].

Variation patterns in the Azores

The samples from the Azores Islands vary from alkali basalts to highly differentiated comendites. Submarine basalts from the Terceira trough are tholeiitic[20]. Initial [87]Sr/[86]Sr ratios from six of the nine islands fall in the narrow range of 0.70332 to 0.70354, and thus are identical to [87]Sr/[86]Sr ratios of basalts from the MAR transect of the platform (Fig. 5). Figure 5 shows also that there is no systematic change in [87]Sr/[86]Sr ratios longitudinally away from the ridge. Both island lavas and tholeiites from the ridge transect of the platform have strontium isotope ratios which are distinct from normal ridge segments.

Flores and Corvo are the only two islands west of the MAR. [87]Sr/[86]Sr values for these two islands range from 0.70332 to 0.70352, with no apparent isotopic differences between the two islands. [87]Sr/[86]Sr ratios from Faial and Pico range from 0.70347 to 0.70394, with values from Faial tending to be somewhat higher than those from Pico. Sao Jorge has [87]Sr/[86]Sr ratios which range from 0.70332 to 0.70354.

Graciosa, Terceira and Sao Miguel lie along the Terceira trough, which may be a secondary spreading centre[4]. Lavas from Graciosa and Terceira, and submarine tholeiites from the trough have [87]Sr/[86]Sr ratios in the range 0.70336 to 0.70354, with the exception of two comendites from Graciosa and
Fig. 3 Sample location map for the Azores Islands. ▲, Sample locations; dotted areas, historical lava flows.

Terceira. The high Rb/Sr ratios, 8 and 10, in the two comendites suggest that their high $^{87}Sr/^{86}Sr$ ratios may be the result of ^{87}Rb decay since differentiation of the magma. If the initial ratios of these two samples were near 0.70350, then the apparent ages are 2.5 Myr for the Graciosa sample and 0.75 Myr for the Terceira sample. Field relationships suggest that these ages may be reasonable.

Sao Miguel, which is apparently located at the intersection of the Terceira, Sao Jorge and Faial–Pico tectonic lineaments[21], is geochemically quite distinct from the other islands. One basalt has an $^{87}Sr/^{86}Sr$ ratio of 0.70337, whereas four other values range from 0.70434 to 0.70525. Samples from Santa Maria have $^{87}Sr/^{86}Sr$ ratios of 0.70336 and 0.70352.

Thus Faial, Pico and, particularly, Sao Miguel are the only islands where initial $^{87}Sr/^{86}Sr$ ratios are markedly dissimilar to those of the adjacent MAR. All these samples are fresh and the high $^{87}Sr/^{86}Sr$ ratios cannot be explained by post-eruptional alteration.

Comparison with Iceland

The maximal $^{87}Sr/^{86}Sr$ and $(La/Sm)_{e.f.}$ values for the ridge transect of the Azores platform (0.70345 and 2.8 (ref. 5) respectively) are considerably higher than values for the ridge transect across Iceland (0.70305 (ref. 12) and 1.3 (ref. 22)

respectively). This is readily apparent for $^{87}Sr/^{86}Sr$ in Fig. 4. Additionally, although the Iceland–Reykjanes Ridge transition zone between the 'undepleted' Icelandic basalts and the 'depleted' ridge basalts extends only some 400 km, the transition zone between the Azores platform and the 'normal' ridge to the south extends some 1,000 km. Thus the geochemical anomaly beneath the Azores is both richer in LIL elements and larger than the anomaly beneath Iceland.

Single or multiple mantle source?

The large scale geochemical gradients along the Reykjanes Ridge reported by Schilling[22], Hart *et al.*[12] and Sun *et al.*[23] have been explained by these authors in terms of mixing of two mantle sources. This model was challenged by O'Hara[24, 25] who suggested that the LIL element variations along the Reykjanes Ridge could be produced by fractional crystallisation. O'Hara[24] dismissed the isotope evidence, stating that the "isotope ratios had changed during the manifest fractional crystallisation." As O'Hara has not yet proposed a mechanism capable of producing such changes and as we know of no evidence to support this contention, we consider it improbable that Sr isotope ratios can be affected by fractional crystallisation.

Other alternatives to the multiple-source interpretation of the data from the Reykjanes Ridge have been based on possible

Fig. 4 Variation of $^{87}Sr/^{86}Sr$ with latitude along the Mid-Atlantic Ridge. Precision is indicated by the error bar (upper left) and is ±0.00006 (±2 s.d.). Measured values for the E and A NBS-SRM 987 standards were 0.70792 ±2 (six analyses) and 0.71017 ±5 (six analyses) (2 s.d. of the mean). All values were normalised to 86/88 = 0.1194 and are reported relative to a value of 0.70800 for the E and A standard. Data previously reported by Hart *et al.*[12] are shown for comparison (+). The dashed line is interpretive.

disequilibrium melting of a phlogopite-bearing mantle[13,26-28]. Disequilibrium melting models such as these are not supported by our results in the Azores region. The correlation of $^{87}Sr/^{86}Sr$ with elevation along the Reykjanes Ridge, on which Flower *et al.*[26] based their model, is poor or nonexistent in the present results. The minimum depth of the rift valley of the MAR transect of the Azores platform is about 1,100 m, yet the strontium isotope ratios of these samples are considerably higher than those of subaereal Icelandic basalts. Sigvaldason's model[27], suggesting that the Iceland mantle plume feeds volcanism in all of the North Atlantic, cannot explain the high $^{87}Sr/^{86}Sr$ values at 45°N and the Azores platform, or the associated gradients.

O'Nions and Pankhurst[13] have developed a disequilibrium melting model for a phlogopite-bearing mantle. A corollary of this model requires that the $^{87}Sr/^{86}Sr$ ratio of the melt should decrease with increasing degree of melting. If alkali basalts are produced by smaller degrees of melting than tholeiites, as suggested by experimental data[29], alkali basalts should have higher strontium isotope ratios than tholeiites derived from the same source. Contrary to this prediction, however, most alkali lavas from the Azores Islands have $^{87}Sr/^{86}Sr$ ratios nearly identical to those of tholeiites from the MAR transect of the Azores plateau. In addition, basalts of tholeiitic composition dredged from the Terceira trough have isotope ratios within the range of alkali basalts from the nearby islands of Terceira and Graciosa.

A number of other serious objections to the disequilibrium melting hypothesis have been raised by Hofmann and Hart[30]. In view of these objections and the above discussion, the disequilibrium melting model seems inapplicable to our results. We conclude that the observed variation in lavas from the

MAR and the Azores Islands does indeed reflect geochemical variation in the mantle.

Any model which attempts to account for the isotopic variation along the ridge must also account for (1) the increases in trace elements and trace element ratios towards the Azores[5,15]; (2) petrological and petrochemical variation along the ridge (ref. 19 and J.-G. S. and W. M. W., to be published); (3) the broadening and shoaling of the MAR in this region; and (4) the thicker crust present beneath the Azores platform by comparison with typical oceanic crust[31].

At present, the model we prefer to account for these observations is that of a mantle plume[5,7] rising beneath the Azores (with a possible separate plume at 45°N) and mixing with the source (depleted in LIL elements) of normal ridge basalts. Reasons for the choice of this model over other models such as a vertically or horizontally heterogeneous static mantle have been discussed elsewhere[3,5,12,15,22]. We interpret the contrast of the alkalic nature of the Azores Islands lavas with the tholeiitic character of basalts from the MAR transect of the platform as being due primarily to differences in conditions of magma generation and evolution, such as depth and extent of melting and subsequent crystal fractionation, rather than differences in mantle source chemistry[29]. These different conditions of magma formation generally produce some enrichment in LIL elements in the melts but do not produce isotopic differences. Higher Sr isotope ratios on Faial, Pico and, particularly, Sao Miguel imply considerable local mantle heterogeneity in this region, however.

Strontium isotope ratios do not decrease longitudinally across the platform (a distance of over 500 km), whereas they begin decreasing along the MAR within 100 to 200 km from the centre of the platform. This asymmetry may result from the fact that although there is mixing of the plume and depleted low velocity layer sources along the ridge, only the plume contributes material to island volcanism. Our analyses of island lavas include both historical flows and flows which are from some of the oldest volcanic sequences of the archipelago (Santa Maria and north-eastern Sao Miguel[32]) and reveal no particular systematic change with time. Thus the plume must have been present beneath the Azores for at least the past 4–6 Myr, and probably longer, judging from rare earth data in DSDP Leg 37 basalts[33].

An enzyme isolated from arteries transforms prostaglandin endoperoxides to an unstable substance that inhibits platelet aggregation

S. Moncada, R. Gryglewski, S. Bunting & J. R. Vane

Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS, UK

Microsomes prepared from rabbit or pig aortas transformed endoperoxides (PGG_2 or PGH_2) to an unstable substance (PGX) that inhibited human platelet aggregation. PGX was 30 times more potent in this respect than prostaglandin E_1. PGX contracted some gastrointestinal smooth muscle and relaxed certain isolated blood vessels. Prostaglandin endoperoxides cause platelet aggregation possibly through the generation by platelets of thromboxane A_2. Generation of PGX by vessel walls could be the biochemical mechanism underlying their unique ability to resist platelet adhesion. A balance between formation of anti- and pro-aggregatory substances by enzymes could also contribute to the maintenance of the integrity of vascular endothelium and explain the mechanism of formation of intra-arterial thrombi in certain physiopathological conditions.

THE prostaglandin (PG) endoperoxides (PGG_2 and PGH_2) are generated from arachidonic acid by the membrane-bound cyclo-oxygenase enzyme[1-3], and subsequently transformed to $PGF_{2\alpha}$, E_2 or D_2 (or to their 15-hydroperoxy or 15-keto derivatives) or to 12-L-hydroxy-5,8,10-heptadecatrienoic acid (HHT) and malondialdehyde[1,3,4]. Recently a novel transformation of PGG_2 and H_2 to a non-prostaglandin compound "thromboxane A_2" (TXA_2) has been reported[3,5], and a microsomal thromboxane synthetase system in blood platelets has been identified and characterised[6,7]. Most of the activity associated with "rabbit aorta contracting substance" or RCS[8,9] is now thought to be due to TXA_2 (ref. 10). TXA_2 shares with prostaglandin endoperoxides two important biological properties; they both contract strips of rabbit aorta[6,7,10,11], and cause platelet aggregation *in vitro*[5,12].

We have discovered that blood vessel microsomes contain an enzyme that transforms PG endoperoxides to an unstable principle which relaxes some blood vessels and prevents platelet aggregation.

Preparation of enzyme and bioassay

Pig or rabbit aortas (one experiment) were stripped of adventitia, snap-frozen in liquid nitrogen, crushed into a fine powder, resuspended (1:4, w/v) in 0.05 M Tris buffer (*p*H 7.5) and homogenised at high speed in a Polytron homogeniser. The homogenate was centrifuged at 1,000*g* for 15 min and the resulting supernatant centrifuged again at 10,000*g* for 5 min. The 10,000*g* pellet was also discarded and after further centrifugation at 100,000*g* for 60 min was resuspended in deionised water and lyophilised. Yield averaged 150 mg powder (51% protein)[13] per 100 g aortic tissue. Electron microscopic examination showed that this fraction was composed mainly of microsomes although there was a small contamination with mitochondria.

Activity of PGs and products of the PG endoperoxides was assayed using the cascade superfusion technique[14]. Tissues were selected from spirally cut strips of rabbit aorta, pulmonary artery, mesenteric artery, coeliac artery and vena cava, as well as rat stomach strip, rat colon, chick rectum, guinea pig ileum and guinea pig tracheal chain. These were superfused in cascade with Krebs' solution (at 37 °C) at 10 ml min⁻¹, containing a mixture of antagonists[15] and indomethacin (1 µg ml⁻¹). Changes in length of the tissues were detected using Harvard smooth muscle transducers and recorded at an overall magnification of 1–4 times on a Watanabe six-channel pen recorder.

The most useful selection of assay tissues was rabbit aorta, rat colon and rat stomach. Rabbit aorta is contracted by PG endoperoxides and TXA_2 but not by PGE_2, $PGF_{2\alpha}$ or PGD_2. Rat colon is contracted by PGE_2 and $PGF_{2\alpha}$ but not by PGH_2, PGG_2 or TXA_2 (refs 9 and 16). Rat stomach strip is contracted to different degrees by all of the above substances.

Aortic microsomes (10–1,000 µg) were incubated with substrate in 100 µl 0.05 M Tris buffer (*p*H 7.5). No cofactors were added. The following substances were tested as substrates: arachidonic acid (1–10 µg ml⁻¹), prostaglandins E_2, $F_{2\alpha}$, D_2, G_2 and H_2 (0.1–1.0 µg ml⁻¹). Reaction sets were incubated

Fig. 1 Bioassay using rabbit aortic strip (*a*) and rat colon (*b*). PGE_2 contracts rat colon whereas PGG_2 contracts rabbit aorta. PGG_2 (0.5 µg) was incubated in 0.5 ml Tris buffer (0.5 M, *p*H 7.5) at 22 °C, and 100-µl aliquots were tested on the tissues at 5, 10, 20 and 30 min. The spontaneous disappearance of PGG_2 (decrease in rabbit aorta contraction) was associated with an appearance of PGE- and F-like activity (increase in rat colon contraction).

Incubation time (min)
Fig. 2 Effect of aortic microsomes (AM) on PGG_2. PGG_2 (0.5 µg) was incubated with AM (1 mg) in 0.5 ml of Tris buffer (0.05 M, pH 7.5) at 22 °C and 100-µl aliquots were tested for activity on the tissues at 0.5, 10 and 20 min. *a*, Rabbit aortic strip; *b*, rat colon. In the presence of AM the contractile activity of PGG_2 on rabbit aortic strip disappeared within 0.5 min but no PGE- or F-like activity was formed even when incubated for 20 min. Boiled AM (200 µg) incubated with PGG_2 (100 ng) in 100 µl Tris buffer at 22 °C for 1 min did not affect activity of PGG_2 on rabbit aorta. The last section shows the selective effect of $PGF_{2\alpha}$ on the rat colon.

for 0.2–30 min at room temperature (20–22 °C). Aliquots of the incubation mixture were tested directly on the assay tissues to detect changes in activity induced by the enzyme. PGG_2 and PGH_2 are unstable in aqueous solution, with a half life of 7–8 min at 22 °C (ref. 7). As they decompose (Fig. 1), so the activity on rabbit aorta decreases and PGE- and F-like activity on rat colon increases.

When incubated with aortic microsomes (3–4 mg ml^{-1}) for 0.25–0.5 min at 22 °C, the contractor activity of PGG_2 or PGH_2 (1 µg ml^{-1}) disappeared, without any increase in PGE- or F-like activity on the rat colon (Fig. 2). There was also no increase in malondialdehyde formation, as estimated by the thiobarbituric acid method[17]. The endoperoxides were transformed, however, into a substance with a different spectrum of biological activity. For convenience, we shall refer to this unknown substance as PGX.

PGE_2, $PGF_{2\alpha}$, PGD_2 (0.5–5 µg ml^{-1}) or arachidonic acid (1–25 µg ml^{-1}) were incubated with aortic microsomes for up to 30 min at 22 °C; since there was no detectable change in biological activity, it was concluded that these substances were not substrates for the enzyme which generates PGX.

The enzymic nature of the transformation by aortic microsomes of PGG_2 and PGH_2 to PGX was substantiated by the following observations: boiled microsomal preparations had no activity, and non-enzymic proteins (for example, bovine serum albumin) did not affect the spontaneous decay of PGH_2 during 1 min of incubation.

Effects of PGX

PGX (100 ng), whether extracted (see below) or not, did not contract strips of rabbit aorta, pulmonary artery or vena cava. PGX relaxed strips of rabbit mesenteric and coeliac arteries. PGX contracted rat stomach strip, chick rectum, guinea pig tracheal chain and guinea pig ileum, although its potency was less than that of PGH_2 or PGG_2. Rat colon was not contracted by endoperoxides or by PGX (100 ng), except after

spontaneous decomposition of the prostaglandin endoperoxides (Fig. 1), when there was a 25–40% conversion to PGE- or F-like substances.

Aggregation of platelets in 1 ml fresh human platelet plasma (PRP) was monitored in a Born aggregometer[18]. Platelet aggregation was induced by arachidonic acid (100–600 µg or 0.3–1.8 mM). Aortic microsomes (5 mg) were incubated with 1 µg endoperoxide (PGG_2 or PGH_2) in 1 ml 0.05 Tris buffer (pH 7.5) for 2 min at 22 °C. Doses of PGX stated below assume complete conversion of the endoperoxide. An aliquot containing 0.25–10 ng PGX was added to the PRP 0.5–1 min before the aggregatory agent. In another set of experiments the products formed during incubation of aortic microsomes with PGG_2 or PGH_2 (incubation time 1–2 min at 22 °C) were rapidly extracted with ice-cold diethyl ether. After evaporation of the ether the residue was either dissolved in ice-cold Tris buffer and immediately used in platelet aggregation studies or was dissolved in anhydrous acetone and stored at −20 °C for future use. These extracts were added to PRP 1 min before the aggregatory agent.

An immediate anti-aggregatory effect of the fresh reaction mixture of aortic microsomes with PGH_2 or PGG_2 was observed. The lowest anti-aggregatory concentration was obtained at concentrations of 0.5–5 ng PGX ml^{-1}. PGX was about 30 times more potent than PGE_1 and 5–20 times more potent than PGD_2 as an anti-aggregatory agent (Fig. 3). PGX was unstable and its anti-aggregatory activity disappeared after standing for 20 min at 22 °C or after boiling for 0.2 min. Aortic microsomes (50 µg ml^{-1}) alone could induce aggregation in some PRP. The products of spontaneous degradation of PGG_2 (100 ng ml^{-1}) had no anti-aggregatory activity.

Diethyl ether extracts of PGX also inhibited platelet aggregation induced by arachidonic acid. The effective anti-aggregatory concentrations of the extracted PGX ranged from 1–10 ng ml^{-1} (assuming complete extraction into ether and complete dissolution in Tris buffer).

The anti-aggregatory activity of the extracted PGX disappeared on boiling (15 s) or on standing at 22 °C for 20 min, but did not deteriorate when the buffered solution was kept on ice for 2 h or when the substance was dissolved in dry acetone and stored at −20 °C for several days.

PGX is different from the other products of PG endoperoxides so far described. Its biological properties on the isolated tissues, its instability and its potent anti-aggregatory activity distinguish it from PGE_2, $PGF_{2\alpha}$, TXA_2 or TXB_2. PGE_2,

Fig. 3 Transformation of PGG_2 activity by different concentrations of aortic microsomes, incubated with 100 ng of PGG_2 in 100 µl Tris buffer for 1 min at 22 °C, and bioassayed using rabbit aortic strip. The reduction in contractile activity of PGG_2 was calculated from the standard dose–response curve for PGG_2 as the percentage transformation of the endoperoxide. Each point on the graph represents the mean ±s.e. of five–seven experiments.
Fig. 4 The tracings show changes in light transmission through platelet-rich human plasma in a Born aggregometer. Comparison of anti-aggregatory potencies of PGX and PGE₁. PGX was obtained by incubation of 100 ng PGH₂ with 500 µg of aortic microsomes in 100 µl 0.05 M Tris buffer (pH 7.5) for 2 min at 22 °C and then stored on ice PGX and PGE₁ (10 µl) were added to human platelet-rich plasma 1 min before arachidonic acid (AA 1 mM). In this experiment PGX was at least 25 times more potent as an anti-aggregatory agent than PGE₁. Doses of PGX (1–4 ng) or PGE₁ (50 ng) are shown at the sides of the tracings.

PGF$_{2\alpha}$ and PGD$_2$ were not substrates for aortic microsomes, so that 15-keto PGs or other products of PG catabolism could not be considered as PGX. PGX is also unlikely to be a 15-hydroperoxy PG, because, firstly, 15-OOH PGE$_2$ contracts rabbit aorta[4], and, secondly, the product(s) of the spontaneous decay of PGX when bioassayed did not behave like PGE$_2$, PGF$_{2\alpha}$ or PGD$_2$. Lack of increased malondialdehyde formation from PGG$_2$ and PGH$_2$ excluded their enzymic transformation by aortic microsomes to HHT.

The presence of prostaglandin D$_2$ isomerase in homogenates of several tissues has been described[5]. Prostaglandin D$_2$ is a potent inhibitor of platelet aggregation[19]. PGX is, however, not PGD$_2$ because PGX is unstable and is a more potent anti-aggregatory agent than PGD$_2$. Besides, PGD$_2$ isomerase is present in the 100,000g supernatant[5], a fraction that in our experiments did not produce PGX from endoperoxides. Moreover, PGD$_2$ isomerase needs glutathione as a cofactor[5] and our incubations were carried out in the absence of cofactors.

The prostaglandin endoperoxides (PGG$_2$ and PGH$_2$) aggregate platelets[10,11] and this activity is probably mediated, wholly or partly, by the enzymic conversion of endoperoxides by platelet microsomes to the less stable TXA$_2$ (refs 6 and 7). Blood vessel microsomes transform endoperoxides to another unstable principle (PGX) which, contrary to TXA$_2$, has potent anti-aggregatory properties and relaxed, rather than contracted, vascular strips. Thus a balance between the amounts of TXA$_2$ formed by platelets and PGX formed by vessels might be critical for thrombus formation. Indeed, in the light of the discovery of this anti-thrombotic property associated with arterial walls, it is interesting to recall the

pre-Lister vitalistic view that in some way the arteries kept the blood fluid. Certainly, platelets adhere easily to any particle or surface, with the unique exception of the vascular endothelium. Generation of PGX by vessel walls could be the biochemical mechanism underlying their ability to resist platelet adhesion. Indeed, platelets attempting to stick to vessels may be releasing PGG$_2$ or PGH$_2$ which is then used by the vessel to generate PGX which prevents the platelets from sticking. Plaque formation on the arterial wall could hinder access of platelet endoperoxides to the PGX-generating system (or of any continuously formed PGX to the platelets) thereby enabling platelet deposition to occur.

PGX may also have other properties. It is well known that platelets repair lesions in the vascular endothelium[20]. An infusion of a small number of platelets is sufficient to restore vascular integrity in the damaged vessels of thrombocytopenic animals[21,22]. Studies of ultrastructure have revealed that platelets can be assimilated into the vascular endothelium or even incorporated into endothelial cells[23,24]. Biochemical cooperation between platelets and vascular endothelium in the generation of PGX could well contribute to the repair of vascular endothelium.

The fact that PGX is locally generated in the arterial wall and can relax arterial smooth muscle also suggests that it plays a part in the local control of vascular tone. A deficiency of PGX could, therefore, underly some forms of hypertension. It will be interesting to find out whether other tissues can also generate PGX and what other biological properties are associated with this class of compound.

We thank Dr F. Ubatuba for preparing the prostaglandin endoperoxides.

letters to nature

A secular relativistic change in the period of a binary pulsar

THE discovery of the first binary radio pulsar PSR1913+16 by Hulse and Taylor[1] stimulated an interest in using relativistic effects to calculate more details of this system.[1–4] It was shown, for example, that observations of the apsidal motion could

allow the masses of the pulsar and its companion to be calculated. There are many mechanisms which could cause a secular change in the observed period of a binary pulsar (for example, mass exchange magnetic friction, electromagnetic radiation). Here we would like to discuss another possibility related to a change of orbital parameters of a pulsar in a binary system and we also estimate the effect of the emission of gravitational radiation on the period of the binary.

Let the intrinsic period of a pulsar be P_0, its orbital velocity v and the mass of the central star M_0; then the observed period P, neglecting the relative motion between the centre of mass of the binary system and the observer, is given by

$$P = \frac{P_0}{(1-(v/c)^2)^{1/2}(1-(2GM_0/c^2a))^{1/2}} \qquad (1)$$

where a is the semi-major axis of the relative orbit, G the gravitational constant and c the velocity of light. For simplicity we will assume that the pulsar moves in a circular orbit. Using Kepler's law to calculate the orbital velocity of the pulsar and keeping only first-order relative corrections, we get

$$P = P_0\left(1 + \frac{GM_0}{c^2a}\frac{3M_0 + 2M_p}{2(M_0 + M_p)}\right) \qquad (2)$$

where M_p denotes the mass of the pulsar.

Let T be the period of the binary system, then

$$\langle P \rangle = \frac{1}{T}\int_0^T P\,dt$$

is the mean period of the pulsar over the period of the binary system. Assuming that there is no mass exchange and M_0 and M_p are constant for the relative time variation of the period we obtain

$$\frac{\dot{P}}{\langle P \rangle} = -\frac{3M_0 + 2M_p}{2(M_0 + M_p)}\frac{GM_0}{c^2a}\frac{\dot{a}}{a}$$

From Kepler's law it follows that when the masses of the components are constant, the relative time variation of the semimajor axis is related to the time variation of the period of the binary system by

$$\frac{\dot{a}}{a} = \frac{2}{3}\frac{\dot{T}}{T} \qquad (4)$$

so finally we have the relationship

$$\frac{\dot{P}}{\langle P \rangle} = -\frac{3M_0 + 2M_p}{3(M_0 + M_p)}\frac{GM_0}{c^2a}\frac{\dot{T}}{T} \qquad (5)$$

Recently, Taylor *et al.*[5] obtained more accurate values of P and T for the pulsar PSR1913+16, giving $\dot{P}/\langle P \rangle = 1.49 \times 10^{-16}$ and $\dot{T}/T = 7.1 \times 10^{-15}$. Substituting probable values of masses $M_0 = 1.41M_\odot$ and $M_p = 1.41M_\odot$ and taking $a = 9.89 \times 10^{10}$ cm, for a ratio between $\dot{P}/P$ and $\dot{T}/T$ we obtain 1.75×10^{-6}. It therefore follows that for the pulsar PSR1913+16 the change in the period is caused by some mechanisms other than the change in orbital parameters.

Using equation (5), in principle, one should be able to detect the change in the period of a binary pulsar caused by the emission of gravitational waves. Landau and Lifshitz[6] calculated the change in semimajor axis of a binary system caused by the emission of gravitational radiation and obtained

$$\frac{\dot{a}}{a} = -\frac{64G^3 M_0 M_p(M_0 + M_p)}{5a^4c^5}$$

substituting this in (3) we have

$$\frac{\dot{P}}{\langle P \rangle} = \frac{32G^4 M_0^2 M_p(3M_0 + 2M_p)}{5c^7a^5} = \frac{2}{5}\left(\frac{R_g}{a}\right)^2\frac{r_g}{a}\left(3\frac{R_g}{a} + 2\frac{r_g}{a}\right)\frac{c}{a} \qquad (7)$$

where R_g is the gravitational radius of the central star and r_g is that of the pulsar. For PSR1913+16 we get $\dot{P}/\langle P \rangle = 1.9 \times 10^{-22}$ s^{-1}, a value which is unobservably small. In a favourable situation, however, with more massive stars forming a compact binary system, the change in the period of the pulsar should be observable. Let us take, for example, a binary system of two stars, one of which could be a black hole, of masses $M_0 = 15M_\odot$ and $M_p = 2M_\odot$ moving in a circular orbit with $a = 2 \times 10^{10}$ cm, then $\dot{P}/\langle P \rangle = 6.25 \times 10^{-16}$ s^{-1} which should be observable with present-day technology.

Improved upper limits of gravitational deflection of polarised radiation

RECENTLY Harwit *et al.*[1] established upper limits for any polarisation dependence in the bending of radio waves by the Sun's gravitational field. Any differential angular splitting between orthogonal polarisations was shown by VLBI techniques, and from the constancy of the Stokes parameters in the carrier wave from a spacecraft, to be $< 10^{-3}$ and 10^{-6}, respectively, of the total bending. Since the latter technique is not sensitive to a splitting in the tangential direction, whereas interferometry is, development of both methods is important. These experiments form a unique test of the equivalence principle[1].

We report here further interferometer measurements. Fomalont and Sramek[2] have measured the total bending of microwave radiation by the Sun's gravitational field. In this paper we search for any polarisation splitting based on a separate analysis of Fomalont and Sramek's data taken with the four-element interferometer of the National Radio Astronomy Observatory (NRAO). For our analysis fringe phases in orthogonal circular polarisations were kindly provided by these investigators. They observed three small diameter radio sources, 0116+08, 0119+11, and 0111+02, at 2,695 and 8,085 MHz with the 35-km intermediate baseline interferometer, as the Sun passed close to their line of sight.

Although the baseline is nearly two orders of magnitude smaller than the baseline of our previous VLBI measurements, the present experiment has produced improved upper limits to the differential deflection. There are two main factors responsible for this improvement. First, the increased phase stability of the NRAO interferometer, together with the higher correlated flux densities at this angular resolution allow a significant increase in signal-to-noise ratio. Second, we were able to observe the sources at smaller solar elongations: 0116+08 was observed to within $< 1°$ of the Sun, 0119+11 to within nearly 3°, and 0111+02 to within $< 7°$.

The method of analysis was essentially the same as that employed in the VLBI experiment. A fringe phase difference, $\Delta\phi$, between the orthogonal circular polarisations, of the form

$$\Delta\phi = G(\rho)[(B_x \sin A - B_y \sin\delta \cos A)\sin H - (B_x \sin\delta \cos A + B_y \sin A)\cos H + B_z \cos\delta \cos A] + \text{constant}$$

was sought, where B_x, B_y, and B_z are the baseline components in wavelengths, A is the position angle of the splitting, H is the

Table 1 Upper limits to the polarisation splitting

		Tangential splitting		Radial splitting	
		Upper limits on K ($\rho = 1°$) (95% confidence)			
n	Frequency (MHz)	$K_{\text{antielockwise}}$ (10^{-3} arc s)	$K_{\text{clockwise}}$ (10^{-3} arc s)	K_{out} (10^{-3} arc s)	K_{in} (10^{-3} arc s)
1	2,695	70	95	70	60
	8,085	35	65	30	50
2	2,695	110	130	95	75
	8,085	90	70	60	60
3	2,695	165	195	90	50
	8,085	110	60	45	35

Upper limits to the polarisation splitting are given at a solar elongation of 1°. Clockwise tangential splitting is defined as that seen by an observer in which right circular polarisation appears rotated clockwise about the Sun away from left circular polarisation. In outward radial splitting right circular polarisation appears at greater solar elongation than left circular polarisation.

hour angle, and δ is the declination. Any angular splitting, $G(\rho)$, would be expected to depend on the solar elongation, ρ. Simple power law radial dependence of the form $G(\rho) = K\rho^{-n}$ ($n = 1, 2, 3$) was assumed.

No polarisation splitting was observed. Ninety-five per cent confidence upper limits were obtained by calculating χ^2 for various assumed values of the splitting. These upper limits are given in Table 1 for both frequencies, for both tangential and radial splitting, and the different values of n. Three intermediate length baselines were obtained by correlating signals from the 45-foot antenna with those from the three 85-foot antennae. These results were not statistically independent and the baseline yielding the smallest upper limits was chosen. The upper limits in Table 1 are ~50–100 marc s at a solar elongation of 1°.

With observations at low solar elongations, the present observations yield improved upper limits for any radial dependence as strong as ρ^{-3} or stronger. (The previous upper limits of Harwit *et al.*[1] were established for solar elongations of 5° and 7.8°, not 5 R and 7.8 R, as given in Table 1 of ref. 1.)

This work was supported by a grant from the Research Corporation. We extend special thanks to Drs E. Fomalont and R. Sramek of the NRAO for allowing us to carry out this analysis with their data. We thank Dr M. Harwit for valuable advice and discussions. The NRAO is operated by Associated Universities Inc., under contract with the NSF.

Origin of Olympus Mons Escarpment by erosion of pre-volcano substrate

OF all the large shield volcanoes of Mars, Olympus Mons is unique in being fringed by a nearly continuous scarp rising 1–4 km above the surrounding terrain[1,2] (Fig. 1). We present evidence that the scarp was caused by preferential erosion of fragmental cratered terrain material previously adjacent to, and at present underlying the shield volcano. Removal of this material caused undercutting and collapse

of the shield flanks, producing the observed terraces and scarps.

A previous interpretation for the scarp was prompted by the recognition that basaltic lava flows which probably form the flanks of Olympus Mons are very resistant to any aeolian erosion[3]. King and Riehle[4] proposed that the volcano has a layered structure with basaltic lava flows capping a base of ash flow tuff deposits which would be readily erodable by aeolian processes. Such an origin for the scarp is unlikely, since volcanoes with basaltic tops and acidic bottoms are not produced typically by terrestrial igneous processes[5]. Rather, it is common for differentiation within magma chambers of terrestrial basaltic volcanoes to result in late stage eruptions of small volumes of more silicic lavas, as at Mauna Kea, Hawaii[6].

Undercutting such as apparently initiated the formation of the Olympus Mons scarp commonly occurs when an upper resistant layer is left unsupported through the removal of a less competent substrate. It is here proposed that the Olympus Mons substrate is a layer of fragmental rubble (megaregolith) resulting from repeated fracturing and brecciation of the surface by intense meteoritic bombardment. On the Moon, the cratered terrain megaregolith is 2–4 km in thickness[7], and a similar thickness may exist on Mars.

Much of the northern hemisphere of Mars is a smooth lava plain with a lower concentration of craters than the rest of the planet. We propose that this is not caused by any fundamental difference in crustal formation, but rather that the original cratered terrain has been stripped off in some erosional event, and the exposed surface veneered with lavas. It is not understood how this happened, nor why the destruction was limited to the northern hemisphere of Mars. Nonetheless, cratered terrain was removed leaving scattered remnants, and the edge of the cratered terrain is presently undergoing erosion[8]. The northern lowlands of Mars are 2–3 km lower than the southern cratered terrain. This difference in elevation is nearly the same as the height of the Olympus Mons scarp, and about the same as the lunar/martian megaregolith thickness. This implies that the erosional event removed the megaregolith only and did not excavate and remove large quantities of well-consolidated basement rock.

In this model the initial Olympus Mons lavas erupted upon cratered terrain, armouring it against later erosion. Removal of the cratered terrain megaregolith led to the undercutting of Olympus Mons lavas and to the formation of the scarp. Thus, the scarp itself is a relic of earlier erosion and not caused by the present erosional regime which only modifies the original structure. This would account for the previously puzzling contrast between the severe erosion of the scarp and the minor erosion higher up on the flanks of Olympus Mons. In some places (for example, the SW flank) later lavas from Olympus Mons flowed over the scarp, re-establishing the original slope. On
Fig. 1 Complex relationships between Olympus Mons shield volcano and the surrounding lava plain are indicated by the embayment of the eastern flank of the shield and by mantling of the south-west escarpment and plains by shield lavas. The photograph has been computer rectified, enhanced and mosaicked at the Image Processing Laboratory of the Jet Propulsion Laboratory by Karl Blasius and Jim Soha.

the other hand, it seems that lavas from the surrounding plain have lapped on to the eastern flank of the volcano. Thus, Olympus Mons spans the time interval from before the onset of the erosional event to a period more recent than the emplacement of the youngest lavas of the surrounding plain. From crater counts[9,10] this interval is estimated to have been $2 \times 10^8 - 2 \times 10^9$ yr, corresponding to a minimum average eruption rate of $\sim 10^{-3} - 10^{-2}$ km^3 yr^{-1}. For comparison, the eruption rate averaged over the past 70×10^6 yr of the Hawaii–Emperor chain is 1.5×10^{-2} km^3 yr^{-1} (ref. 11).

Neither the volcanoes of the Tharsis plateau nor those of Elysium have scarps such as bound Olympus Mons. According to the hypothesis developed here scarps would not form unless the ancient cratered terrain substrate was eroded away after the initial armouring eruptions. The geological map of the Tharsis region[12] shows 'hilly material', interpreted as remnants of cratered terrain, extending out from under the Tharsis volcanoes. This demonstrates that the cratered terrain was not completely destroyed during the erosion episode and thus, the Tharsis volcanoes were not undercut and did not develop scarps. Similar circumstances occur in the Elysium region. The Elysium dome is fringed by irregular rounded hills[12] which seem to be the erosional remnants of cratered terrain. Apparently, the ancient cratered terrain was not completely removed and thus scarps were not formed in this region.

Correlation of Martian surface heights with latitude of polar hood boundaries

A COMPARISON of Earth-based photography with topographic data from Mariner 9 reveals that the winter polar hoods on Mars tend to extend further towards the equator at lower topographic heights than at higher topographic heights. The correlation between latitude of the hood boundary and topographic heights is shown in Figs 1 and 2. In Fig. 1, contour lines derived from a map by Christensen[1] have been superimposed on the Lowell Observatory map of Martian Albedo Features and Topography[2]. To the author's knowledge, the Christensen map is the only published map that includes contour lines up to 65°N. The dashed lines represent the mean boundary of the polar hoods during twelve apparitions between 1905 and 1958, as determined from a study of Lowell Observatory's historical photographic collection. The southern hood boundary is in close agreement with a map by Capen[3] that was made from measurements of more recent apparitions (1962–68), while the northern boundary agrees well with Mariner imaging[4]. In Fig. 2, the latitude of the hood boundaries (at 10° intervals in longitude) is plotted as a function of topographic height. The dashed line was fitted to the southern latitude points by least squares. The north hood points were then shifted along the ordinate until their average value fell on the dashed line. An equally good, if not better, correlation is found if one plots the latitude of the boundary of the southern hood against atmospheric pressure from the work of Conrath *et al.*[5]. The hood is found to extend farther north over areas of higher pressure than over areas of lower pressure. Comparable atmospheric pressure data are not available for the Northern Hemisphere.

The explanation of the phenomenon reported here is not
Fig. 1 Averaged boundaries for Martian polar hood clouds during northern and southern winters. The seasonal positions of Mars in its orbit that were used are L_s 315°–344° for the north and L_s 135°–164° for the south. The contour lines give heights in kilometres and have been redrawn by C. F. Capen from Christensen[1] on to the Lowell Observatory map of Martian Albedo Features and Topography[2].

Fig. 2 Correlation of surface heights with areographic latitude of the averaged boundaries of Martian polar hood clouds, measured on red- and green-filter photographs from the Lowell collection, taken from 1905 to 1958. The latitudinal scales have been offset to compensate for systematic differences between northern and southern winter hoods. The dashed line was fitted by least squares to the southern hood data. ×, North hood (L_s = 315°–344°); ○, South hood (L_s = 135°–164°).
yet completely clear. Briggs and Leovy[4] have, however, argued that the hood clouds in the zone from 40 to 50°N must be water ice, while Farmer[6] has suggested that the bulk of the water vapour will be found in the lowest atmospheric layers.

A granite cliff deep in the North Atlantic

WE report here preliminary results from the detailed sampling of granitic basement at a depth of 4,000 m at the lower edge of the Armorican continental margin near 48°N and 12°W. We consider that we have sampled here the extreme lateral limit of the continental crust where local exposures emerge from under a cover of Cainozoic, Mesozoic and probable Palaeozoic sediments.

The Goban Spur[1], part of the deep continental margin off France and the UK, lies between the Celtic shelf and the Porcupine abyssal plain ~ 550-km West of Brest and Land's End (Fig. 1). A seismic profile of the continental slope in this area shows a succession of three main 'gradins' (steps) with intermediate sedimentary basins (Fig. 2). The westernmost and deepest of the steps has a steep southwestern slope Granite Cliff 4,000 near the 4,000-m isobath.

• Twenty km further to the south-west is the marginal hill or high named by us Menez Bihan. At each of the three steps the substratum appears as an outcrop, passing under the sedimentary cover of the adjacent basin. The substratum seems to be continuous between the steps; it is 3-s d.t.t. (double travel time) deep to the east of the first step and 8-s d.t.t. deep at the foot of the continental slope (Fig. 2).

In December 1975, with the RV Le Suroït, we dredged fragments of granite from the steep slope we now call Granite Cliff 4,000 (Fig. 2). On the side of King Arthur

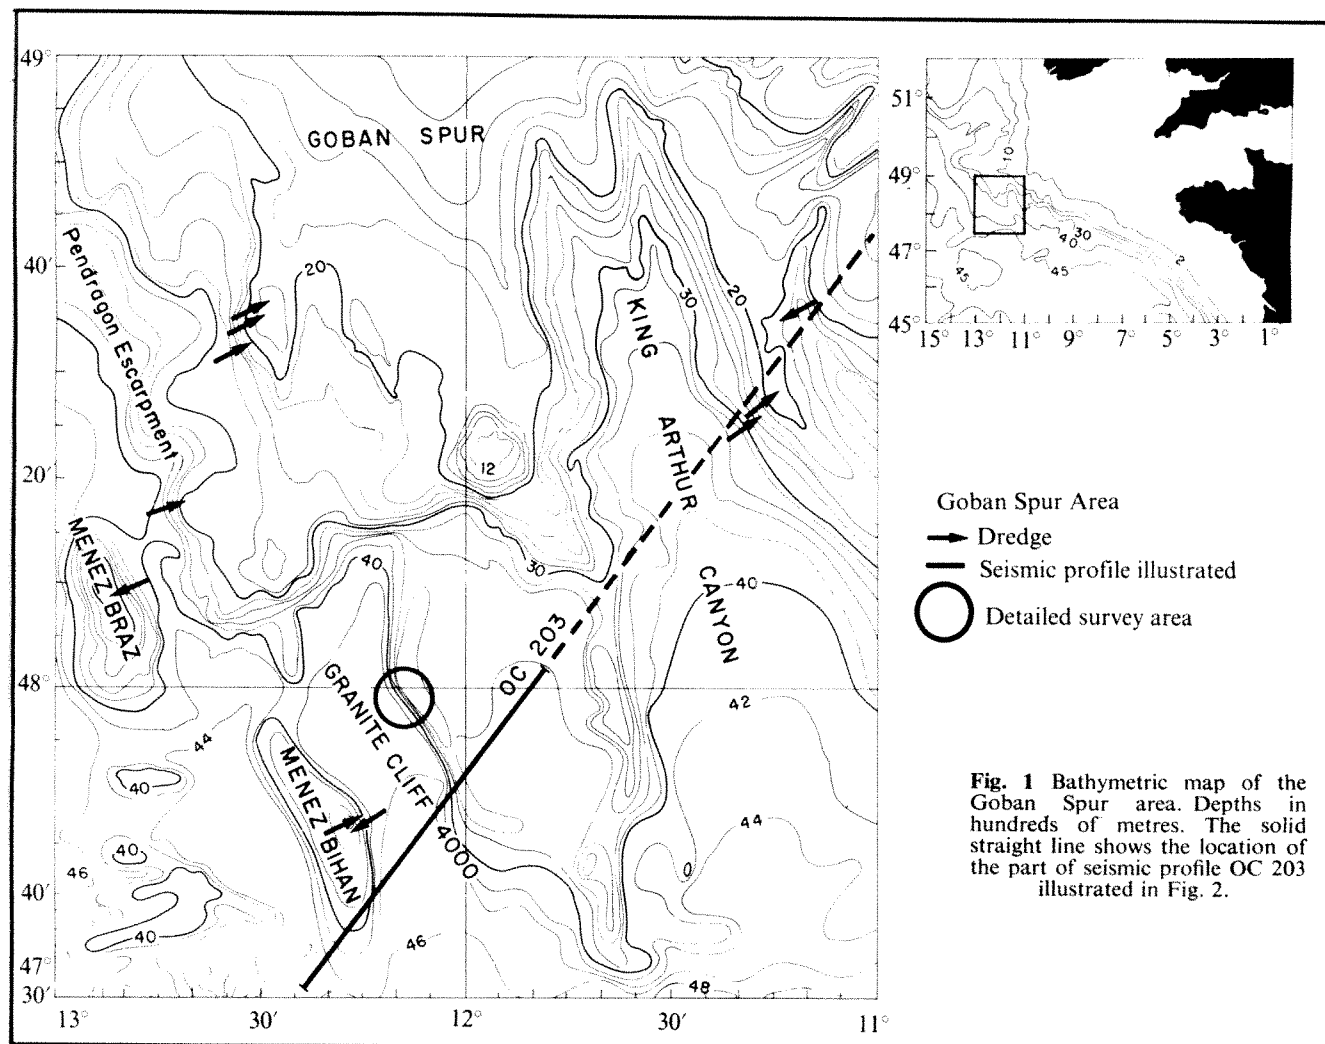
The dip of the slope of Granite Cliff 4,000 reaches at least 30° (the maximum slope which can be detected with the conventional 12-kHz precision depth recorder we used). The base of the slope is very straight in the studied area and this linearity, coupled with the apparent steepness of the slope, suggests that it is a fault escarpment. The foot of the slope is 4,150-m deep and the top lies at 3,150 m. Photographs of the slope show sediments on the lower and upper parts. In between, the sediment cover is thin and there are round outcrops, some of which show fractures.


Fig. 1 Bathymetric map of the Goban Spur area. Depths in hundreds of metres. The solid straight line shows the location of the part of seismic profile OC 203 illustrated in Fig. 2.

Canyon, at a depth of 3,000 m, we dredged a pebble containing fossil material identified as Devonian. To investigate further these findings, and to make sure that the granite dredged was not erratic, we went back to the area in February 1976 with the RV Jean Charcot.

We made a bathymetric survey to clarify the relationship between Granite Cliff 4,000 and Menez Bihan and then moored three acoustic beacons on the bottom: two at the foot of the cliff and one near the top (all within the circle in Fig. 1). The distance between beacons was ~ 6,000 m. On board, on a plotting table, the track of the ship and the track of the dredge (or camera) on the bottom were then followed in real time with a precision of ~ 30 m. In this manner it is possible to visualise the work of the dredge on the bottom and, in combination with the tensiometer, to determine with precision the position of breaking-off of the rocks. For the seafloor photography, we used both a troika (a toboggan that slides on the bottom) and a camera frame attached to the cable just ahead of the dredge.

Four dredgings with the acoustic navigational control were made and in each dredge we found blocks of granitic rock. Their appearance and the dredge-wire tensiometer records indicate that some of the blocks were torn off outcrops, and support the evidence from the seafloor photographs that we are not dealing with ice-rafted erratics, except perhaps for a few associated pieces of dark or light granulite, the autochonous origin of which is still in doubt. In addition, the presence of all the rocks found can be reasonably associated with the setting in which they occur.

The granitic blocks are more or less weathered and are partially covered with ferromanganese crusts up to 12-cm thick. They are granodiorites, tending to quartz diorites. The minerals present are quartz with undulating extinction, biotite (abundant), andesine (abundant, automorphic and zoned), potassic feldspar (rather scarce), apatite, zircon and opaque minerals (J. Didier, personal communication). The fabric is clearly directional, and the biotites are slightly curved.

Menez Bihan

Granite Cliff 4,000
Fig. 2 Seismic profile OC 203 made by the RV Florence. Location of the profile is shown on Fig. 1. Vertical exaggeration is ×5.

Similar rocks possibly a little more altered, were dredged on the flanks of Menez Bihan (Fig. 2). The apparent continuity between Menez Bihan and Granite Cliff 4,000 (Fig. 2) is thus demonstrated. On geomorphic grounds (Fig. 1) it seems probable to us that Menez Braz to the north-west is also granitic, but we obtained no samples because of the considerable thickness of sediment there.

In three areas we dredged fragments of old sedimentary cover lying above the granitic substratum. From the flanks of Menez Bihan we collected a fragment of quartzitic sandstone. The remainder of the dredge-haul was entirely granitic Granite Cliff 4,000 yielded numerous samples of limestones some of them of possible Mesozoic age. On the Pendragon escarpment (Fig. 2), at a depth of between 3,000 and 2,000 m, the dredge recovered no granite, but a few metamorphic rocks and a rich sample of old sedimentary rocks: fine green sandstones, marly chalk with veins of calcite, grey claystone, sedimentary breccias and quartzite. No fauna has been found on preliminary examination, but we speculate that the rocks represent Palaeozoic or even older sediments.

The dredging of 'in place' granitic rocks at 4,000 m is exceptional and has important implications. In geometric reconstructions of the early opening of the North Atlantic, for example, many authors[2] have used a shallower depth (1,000 to 2,000 m) and hence a more easterly limit, for the edge of the continental crust. The maximum depth of the granite is evidently even greater than 4,000 m. Judging from the seismic profile (Fig. 2), the probable continuity of the granitic substratum between Granite Cliff 4,000 and Menez Bihan lies at a depth of 8 s d.t.t. (between 6,500 and 7,500 m).

To the south-west of Menez Bihan lies a low hill above the 4,000-m water depth (Fig. 1). Seismic profiles show that the basement of this hill is rough: quite different in character from that of Menez Bihan. Magnetic records show that the east flank of the low hill marks the beginning of a sharp anomaly (500×10^{-9} T) whereas the magnetic profile on the continental side of the hill is relatively flat. According to C. Williams (personal communication), anomaly 34 (~ 85 Myr) passes close by. The hill does not seem to have the acoustic

character of an intrusion, and may indeed mark the contact between oceanic crust and continental crust[3].

The granodioritic character of the granitic massifs we sampled suggests that they are orogenic granites, presumably of the intrusive type and of deep origin. It is difficult to envisage their emplacement during early rifting (90–100 Myr). None of the granites is alkaline and they are neither porphyritic nor strongly deformed. On the other hand, they may well be late generation (post-phase 2) granodiorites of Hercynian age (J. Didier, personal communication). They may represent intrusions in a granulitic basement which would explain the rocks belonging to the granulitic facies that we dredged from Granite Cliff 4,000 and from Menez Bihan. The basement underlying the continental slope itself is probably not made up of granodiorites. The latter usually appear as intrusions in the Hercynian chains (for example, the Armorican massif).

The oldest sedimentary rocks are epimetamorphic with at least two phases of deformation (folding). They resemble the Palaeozoic and Upper Precambrian (Brioverian) rocks of the Armorican massif (M. Gravelle, personal communication). We interpret this evidence as further support for arguing that the basement underlying the continental margin east of Menez Bihan is probably the older Hercyninan basement (granulite with granodiorite intrusions).

The direction of Granite Cliff 4,000 is similar to the Pendragon Escarpment (N 30° W) and may be related to Hercynian faults[4]. During the rifting phase of the North Atlantic, normal faulting associated with the subsidence of the continental blocks probably reactivated these old features. During the initial uplift phase, Menez Bihan would—in most models—have been on top of the uplifted crust and would consequently have been deeply eroded. Thus it seems reasonable that we dredged granite and Mesozoic limestone on Granite Cliff 4,000 and no Palaeozoic sediments. The upper part of Pendragon Escarpment, further away, was not, however, eroded to such an extent. Subsequently, thermal processes led to inversion of relief, with normal faulting along the Hercynian zone of weakness and subsidence of the continental margin.

• David Needham and Xavier Le Pichon gave us useful advice in their reviews of the manuscript. Jean Didier, Michel Gravelle, Claude Babin and Annick Pelhate made preliminary descriptions of the samples.

Infrared polarisability of hexagonal ice

THE limiting high frequency polarisability, α, of a solid is the algebraic sum of the optical, or electronic, polarisability, α_e, of the ions or molecules, and the infrared polarisability, α_{IR}, caused by the displacement, or vibration, of ions or molecules within the lattice. For most solids both α_e and α_{IR} are independent of volume and temperature, but for a number of ionic solids and for polymorphs of ice, α_{IR} is not so. We describe the temperature dependence of α_{IR} of hexagonal ice, and discuss it in terms of contributions from anharmonic effects.

For an isotropically polarisable material, α is given by the Clausius–Mossotti relationship

$$\frac{4}{3}\pi N\alpha = V\left(\frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2}\right) \qquad (1)$$

where N is Avogadro's number, V the molar volume and ε_∞ the limiting high frequency relative permittivity of the orientation polarisation. V for H_2O ice was calculated for a density of 0.9169 Mg m^{-3} at 270 K, and the average expansivity[1-5] is given in Fig. 1. V for D_2O ice was calculated for a density of 1.0175 Mg m^{-3} at 270 K and Dantl's[3] expansivity data. ε_∞ of H_2O ice for 2–77 K is taken from Gough's data[6] and for 77–273 K from our own[7]. ε_∞ of D_2O ice is known only above 77 K (ref. 8).

α_e for an H_2O molecule in ice is 1.5 Å^3 (ref. 9), and α_e for a D_2O molecule in the liquid phase, calculated from the Lorentz–Lorenz equation, is 1.46 Å^3 (ref. 8), which value is likely to be the same in D_2O ice. α_{IR} ($= \alpha - \alpha_e$) calculated from these values of α and α_e for both the ices is plotted against temperature in Fig. 2, which shows that the infrared polarisability of ice increases with temperature.

$$\alpha_{IR} = \alpha_{0,IR} + AT^2 \qquad (2)$$

where $\alpha_{0,IR}$ is the infrared polarisability at O K and A is an empirical constant. The values of $\alpha_{0,IR}$ and A are 1.64 Å^3 and 2.03 × 10^{-6} Å^3 K^{-2} for H_2O and 1.49 Å^3 and 2.95 × 10^{-6} Å^3 K^{-2} for D_2O ice. The T^2 increase in α_{IR}, which seems unique to hexagonal ice, is attributable to the anharmonicity of mechanical and electrical vibrations of H_2O molecules, as a consequence of which, the force constant of molecular vibrations becomes amplitude and temperature dependent. $\alpha_{0,IR}$ can then
Fig. 1 The isobaric expansivity, γ, of H_2O ice plotted against temperature. The values were interplotted from, $\triangle$, Jacob and Erk[1]; ■, Powell[2], ▲, Dantl[3] for bulk expansion; and are as given by ○, LaPlaca and Post[4]; and ●, Brill and Tippe[5] for lattice constant expansion. The straight line between 30 and 273 K is the 'best' curve, in lieu of a least square fit which seems inappropriate because numerical data from various authors are lacking. Results from refs 2, 4 and 5 have been converted to values for polycrystalline ice.

be interpreted as the infrared polarisability if the lattice vibrations were entirely harmonic, as is anticipated at 0 K.

The anharmonicity of lattice vibrations is also reflected in the temperature dependence of heat capacity and expansivity, and a consideration of the latter is useful in an analysis of the T^2 dependence of α_{IR}. The temperature coefficient of α_{IR} at a constant pressure may be divided into two

$$\left[\frac{\partial \alpha_{IR}}{\partial T}\right]_P = \left[\frac{\partial \alpha_{IR}}{\partial T}\right]_V + \gamma\left[\frac{\partial \alpha_{IR}}{\partial \ln V}\right]_T \qquad (3)$$

where γ is the volume expansivity. $(\partial \alpha_{IR}/\partial T)_V$ constitutes the volume-independent temperature effect and $(\partial \alpha_{IR}/\partial \ln V)_T$ the temperature-independent volume effect.

Because of the lack of an adequate theory of anharmonic effects, the exact relation between γ and T is not known. For ice, such a relation is further uncertain because of the great variation between the reported values of its γ, as evident in Fig. 1. In the range, 30–273 K, γ can still be adequately described by the equation, $\gamma = \gamma_0 + mT$, as shown in Fig. 1, although the linear relationship is not anticipated to hold near 0 K because theory requires that γ should be zero at 0 K. For H_2O ice, $\gamma_0 = -3.6 \times 10^{-5}$ K^{-1} and $m = 7.39 \times 10^{-7}$ K^{-2}. Substituting for γ in equation (3), one obtains

$$\left[\frac{\partial \alpha_{IR}}{\partial T}\right]_P = \left[\frac{\partial \alpha_{IR}}{\partial T}\right]_V + \gamma_0\left[\frac{\partial \alpha_{IR}}{\partial \ln V}\right]_T + m\left[\frac{\partial \alpha_{IR}}{\partial \ln V}\right]_T T \qquad (4)$$

By differentiating equation (2)

$$\left(\frac{\partial \alpha_{IR}}{\partial T}\right)_P = 2AT \qquad (5)$$

A comparison of equations (4) and (5) suggests that, unless $(\partial \alpha_{IR}/\partial T)_V$ is a linear function of temperature

$$\left(\frac{\partial \alpha_{IR}}{\partial T}\right)_V = -\gamma_0 \left(\frac{\partial \alpha_{IR}}{\partial \ln V}\right)_T$$

and

$$\left(\frac{\partial \alpha_{IR}}{\partial \ln V}\right)_T = \frac{2A}{m}$$

For H_2O ice, using values of A and m given above, $(\partial \alpha_{IR}/\partial \ln V)_T = 5.49$ Å^3 and $(\partial \alpha_{IR}/\partial T)_V = 1.98 \times 10^{-4}$ Å^3 K^{-1}.

The contribution to $(\partial \alpha_{IR}/\partial T)_P$ in equation (3) from a temperature change alone, $(\partial \alpha_{IR}/\partial T)_V$, is positive for ice, as it is for ionic crystals of NaCl structure[10], but the contribution from a volume change, $\gamma(\partial \alpha_{IR}/\partial \ln V)_T$, is negative at $T < 50$ K and positive at $T > 50$ K, because γ changes sign near 50 K (Fig. 1). Near 273 K, $\gamma(\partial \alpha_{IR}/\partial \ln V)_T$ increases to nearly 4 $(\partial \alpha_{IR}/\partial T)_V$. Thus the difference between the respective temperature variation of α_{IR} at constant volume and constant pressure is substantial near 273 K and all of the increase in α_{IR} (and ε_∞) with temperature results from the associated volume change rather than to any explicit dependence on temperature.

As the nonlinear effects of anharmonic terms in the intermolecular potential, responsible for expansivity, are anticipated to disappear near 0 K, $\gamma \to 0$ as $T \to 0$ K. Therefore $(\partial \alpha_{IR}/\partial T)_V \to 0$ at 0 K as does $(\partial \alpha_{IR}/\partial T)_P$. A complete analysis of the interesting features of α_{IR} in the low temperature range would require accurate values of γ, $(\partial \alpha_{IR}/\partial T)_V$ and $(\partial \alpha_{IR}/\partial \ln V)_T$, not available at present. The validity of the relation between α_{IR} and T^2 for ice, however, is not likely to be significantly affected by a possible negative value of γ below 50 K, for the data points below 50 K lie in a relatively small range of T^2, as shown in Fig. 2.

The pressure dependence of α_{IR} and ε_∞ of ice can be predicted from

$$\left[\frac{\partial \alpha_{IR}}{\partial P}\right]_T = -\beta \left(\frac{\partial \alpha_{IR}}{\partial \ln V}\right)_T \qquad (6)$$

where β is the compressibility. For H_2O ice $\beta = 12 \pm 1$ Mbar^{-1} (ref. 11) at $20 < T < 273$ K, and therefore $(\partial \alpha_{IR}/\partial P)_T = -65.9$ Å^3 Mbar^{-1}.
By differentiating equation (1) with respect to pressure, one obtains

$$\left(\frac{\partial \varepsilon_\infty}{\partial P}\right)_T = \frac{1}{3}(\varepsilon_\infty + 2)(\varepsilon_\infty - 1)\left[\beta + \frac{1}{\alpha_{IR}}\left(\frac{\partial \alpha_{IR}}{\partial P}\right)_T\right] \qquad (7)$$

At 270 K, $\varepsilon_\infty = 3.19$ (ref. 7), and therefore from equations (6) and (7), $(\partial \varepsilon_\infty/\partial P)_T = -94$ Mbar^{-1}. Thus, both the ε_∞ and α_{IR} of ice are anticipated to decrease by $\sim 3\%$ kbar^{-1} near 270 K.

γ (ref. 3) and β (ref. 11) for H_2O and D_2O ice are the same and at 270 K, $\varepsilon_\infty = 3.09$ (ref. 8) for D_2O ice. The analysis of α_{IR} for D_2O ice thus gives: $(\partial \alpha_{IR}/\partial \ln V)_T = 7.98$ Å^3, $(\partial \alpha_{IR}/\partial T)_V = 2.87 \times 10^{-4}$ Å^3 K^{-1}; $(\partial \alpha_{IR}/\partial P)_T = -95.8$ Å^3 Mbar^{-1} and $(\partial \varepsilon_\infty/\partial P)_T = -156$ Mbar^{-1}. The decrease in α_{IR} and ε_∞ on application of pressure is, therefore, anticipated to be $\sim 60\%$ more in D_2O than in H_2O ice.

The magnitude of the contribution to ε_∞ from vibrational polarisation is directly related to the negative second moment of the absorptivity, according to the Kramers–Kronig relationship (see ref. 7 for details). It follows that the application of pressure should either increase the frequency of the major absorption bands and/or decrease the absorptivity of the infrared radiation in ice.

The above conclusions are of significance because measurements of both ε_∞ and the infrared spectra of hexagonal ice with pressure are difficult, and because it is widely assumed that the application of pressure should increase ε_∞ of ice.

T (K)

Fig. 2 The infrared polarisability, α_{IR}, of $\bigcirc$, H_2O and $\bullet$, D_2O ice plotted against the square of temperature. The relation between α_{IR} and T^2 is little affected by the variation in the reported values of γ seen in Fig. 1.

The valence of transition metal atoms in metallic alloys

THE 'valence' of transition metal atoms in metallic alloys has long been and still is a source of controversy. On the one hand, there are measurements such as those of Haworth and Hume-Rothery[1] which indicate quite small valences, there are electron concentration rules in numerous Hume-Rothery β and γ phases which indicate 'zero' valences, and there are measurements (for example, Coppens[2]) which even indicate 'negative' valences, whereas on the other hand, melting points, hardness and heats of atomisation indicate much higher valences. In this paper we point out that the valence of a transition metal atom in a metallic alloy cannot usefully be described by a single number. Three parameters are required: the number of outer electrons contributed to partly filled energy bands, the number entering filled bands lying below the Fermi level, and a parameter $(0 < \alpha < 1)$ describing the effectiveness for cohesion of the hybridisation of the filled bands originally derived from d states with those originally derived from s and/or p states.

This is because the valence electrons contributed by the transition metal may become part of two distinct groups which have different properties. The number and properties of electrons in one group—partly filled sheets of Fermi

surface (partly filled energy bands)—can be explicitly measured in suitable cases, whereas the properties of the other group—electrons in filled energy bands lying below the Fermi level—are always seen with those of the other group. Thus the valence of a transition metal atom in a metallic alloy cannot usefully be described by a single number. One parameter is required to specify the number of electrons contributed to partly filled energy bands in the alloy, another to describe those contributed to filled energy bands which have mainly d character. A further parameter, $0 < \alpha < 1$, is required to describe the effectiveness of the hybridisation of the filled bands originally derived from d states with those originally derived from s (and/or p) states, which ensures that the electrons are cohesive ($\alpha > 0$) even though they lie below the Fermi level. Such a description does not seem to be basically different to a valence bond description that considers the formation of hybridised bond orbitals which are derived from d, s and/or p states (see, for example, Pauling[3]; Altman, Coulson and Hume-Rothery[4]), but it does have the advantage when applied to metallic alloys of allowing one to recognise the difference between the numbers of itinerant electrons in partly filled energy bands and those in filled energy bands, which give the differences in physical measurements or estimates of valence referred to above.

Thus it is obvious that in determining the valence of Mn, Fe, Co and Ni from phase boundaries in certain alloys, Haworth and Hume-Rothery[1] were measuring properties controlled by the number of electrons contributed by the transition metals to the partly filled bands. In β and γ brass-type phases where many transition metals are said to be 'zero valent' to satisfy electron concentration rules, the outer electrons of the transition metal atoms are in filled bands below the Fermi level and the valence electrons contributed by the other component are sufficient to provide the required electron concentration in the partly filled bands. This is confirmed by the similarity of the Fermi surface of β-PdIn to those of β-AgZn and β-CuZn, indicating in each case, three electrons in partly filled sheets of Fermi surface in Brillouin zones one and two (Jan, Pearson and Saito[5]). Since indium contributes three valence electrons, the 10 outer electrons of Pd can be regarded as occupying filled bands below the Fermi level, and 'zero valence' is to be interpreted as contributing no net electrons to the conduction bands. Similarly an apparent negative valence of a transition metal is interpreted as retention of some of the valence electrons contributed by the other alloying component(s) in filled bands below the Fermi level, so that the electron concentration in partly filled sheets of Fermi surface (conduction bands) is reduced below the number of electrons contributed by the other alloying component(s).

The melting points of the transition metals and their heats of atomisation generally rise to a maximum in the fifth or sixth Group where the most effective cohesion from the outer electrons, is obtained. Although Fermi surface studies show the noble metals, Cu, Ag and Au, to have only one electron in partly filled bands, the high melting points (1,083 °C for Cu) and the heats of atomisation (81.1 kcalorie per gram atom at 298.15 K for Cu (Brewer[6])) indicate far more cohesion than that obtained from one outer electron (20–30 kcalorie per gram atom in heat of atomisation). This extra cohesion comes from hybridisation of the bands derived from d states with those derived from s and p states so that they contribute to cohesion even though they are full and lie below the Fermi level. The low melting point and the heat of atomisation of Zn (31.2 kcalorie per gram atom at 298.15 K (Brewer[6])), however, correspond to the two outer electrons in partly filled bands and indicate virtually no remaining hybridisation of the d bands to contribute to cohesion (that is $\alpha \sim 0$).

In summary, then, if V_i represents the number of outer electrons contributed by the transition metal to partly filled energy bands and V_1 the number contributed to filled energy bands, V_i may, in favourable cases, be determined from measurements of properties sensitive to the electron concentration in partly filled energy bands (Fermi surface, phase boundaries, etc.) and the number of valence electrons contributed by a non-transition element in the alloy. In considering properties such as melting points and cohesive energy, the contributions of both αV_1 and V_i are to be considered. Thus, for example, although electron concentration rules indicate $V_i \sim 0$ in β-brasses such as AlCo or AlNi, their high melting points (1,645 and 1,638 °C respectively) indicate a sizeable value of αV_1, which with the three electrons per formula unit contributed by Al, gives the large cohesive energy. The classical chemical valences of the transition metals (2+, 3+, etc.) are normally found in compounds with filled energy bands that are insulators or semiconductors.

The glass transition temperatures of phosphoric acids

THE vitrification of phosphoric acids is relatively easy, a glass often being formed simply on cooling from the liquid melt. Special procedures, however, are required to crystallise these materials. The glass transition temperature, T_g, is the temperature above which there is relatively rapid molecular motion; below T_g translational motion of molecules is inhibited. In standard texts[1] it is stated that the glass transition temperature of orthophosphoric acid, H_3PO_4, is -121 °C. The source of the determination is not always cited but it seems to be that of Kobeko *et al.*[2] who determined T_g from measurements of the temperature dependence of the electrical conductivity of phosphoric acid. Although published almost 40 yr ago there does not seem to have been a more recent determination. We present here evidence from broad-line nuclear magnetic resonance (NMR) studies that the estimate of -121 °C for the glass transition temperature of ortho-phosphoric acid is wrong. A discussion of the interpretation of the electrical conductivity of phosphoric acid would be inappropriate beyond observing that several different ionic or molecular processes may be responsible for the transfer of electrical charges. Thus, an unambiguous determination of a glass transition from such data may be far from straightforward.

Broadline NMR spectra are obtained when solids or viscous liquids are studied, and the linewidth, δH, can be interpreted as a measure of the extent of molecular motion. With the onset of molecular motion the linewidth is reduced; this is because of the averaging effect of local molecular motion on the magnetic field 'seen' by the nuclei, such as the protons in the phosphoric acids.

In Fig. 1 typical proton NMR, ^1H, spectra are given for a sample prepared by dehydration at 300 °C of analytical reagent grade phosphoric acid, 85–90% H_3PO_4. Experimental methods used for the measurement of the NMR spectra are similar to those used for the determination of the T_g of α-D glucose penta-acetate and epoxy resins[3,4].

In experiments such as these the NMR linewidth is determined by the spin–spin relaxation time, T_2, and the linewidth, δH, is inversely related to this relaxation time

$$\delta H = \frac{\text{const}}{\gamma T_2}$$

where δH, the linewidth, is measured between the maxima and minima of the first derivative of the absorption signal (Fig. 1) γ is the gyromagnetic ratio and the value of the constant depends on the line shape[3,4].
Fig. 1 First derivatives of NMR absorption spectra for phosphoric acid with $R = H_2O/P_2O_5 = 1.17$. *a*, Rigid glass at 169 K ($-104\,°C$). *b*, Fluid liquid at 302 K (29 °C). The linewidth was determined from at least six repeat spectra. The spectrometer modulation was $\sim 1/5\,\delta H$ to avoid modulation broadening of the spectra. Measurements taken from ref. 6.

The change in linewidth with temperature for a phosphoric acid glass forming system is given in Fig. 2. At low temperatures the linewidth is large because of dipolar broadening because of the presence of other nuclei with magnetic moments. Thus, the linewidth is essentially determined by the local magnetic fields, H_{loc}, which depend on the local arrangements of neighbouring protons. When the temperature is raised sufficiently to permit molecular motion, the time average local magnetic field, $\langle H_{loc}\rangle$, is reduced. From NMR theory it is shown that relaxation processes have longer T_2 relaxation times when molecular motion occurs, and hence the linewidth δH decreases when T_2 increases.

Several methods have been proposed for the determination of glass transition temperatures from the change of linewidth with temperature[8], all of which yield essentially the same estimate of T_g when the transition is 'sharp'. The inflection point of the δH against T curve (Fig. 2) was used to estimate T_g for these phosphoric acid glasses. The transition illustrated in Fig. 2 is very sharp.

For specification of glass transition temperatures it is essential to include the experimental procedure in the operational definition of T_g, as was pointed out by Gee $\sim 10\,\mathrm{yr}$ ago[5]. Maklakov and Pimenov[8] have discussed the relationships between NMR line narrowing and other methods of estimating T_g and McCall[9] has commented on NMR measurements of relaxation behaviour and the theories of glass transition behaviour. For the present purposes the inflection point
Fig. 2 NMR linewidth against temperature for phosphoric acid with $R = 1.33$. The glass transition temperature T_g is determined from the inflection point in the transition region[6].

of the NMR linewidth against temperature curve will be defined as the glass transition temperature, that is, $T_i = T_g$.

There are several theoretical empirical mixture rules for the correlation of the glass transition temperatures of two component systems[10], but none are established unequivocally. Thus, to represent the effect of composition of phosphoric acids on their glass transition temperatures it is convenient to plot T_g against R, where R is the molar ratio of H_2O/P_2O_5. Use of this compositional variable allows inclusion of metaphosphoric acid HPO_3, $R = 1$, and normal laboratory reagent 85–90% orthophosphoric acid, $R \simeq 4$. From Fig. 3, it is clear that there

Fig. 3 Glass transition temperatures against R. T_g was determined from NMR linewidth against temperature graphs as in Fig. 2. The straight line was fitted by a linear regression procedure with the assumption that R was error free and all the error is in T_g, its equation is $T_g = 281.1 - 17.28\,R$, $1 \leqslant R \leqslant 4$. The correlation coefficient is 0.99_3. Data from ref. 6, $R = 1.17$ and 1.33; ref. 7, $R = 2.10, 2.78$ and 3.95; $R = 2.18$ (unpublished data of B.E. and N. A. Miller), ▲., ref. 11; ●, ref. 2.
is a linear relationship between T_g and R, when T_g is determined from the inflection point of the proton NMR linewidth temperature curve.

For the metaphosphoric acid, HPO_3 with $R = 1$, T_g has been determined by Eisenberg[11] using a linear variable differential transformer to measure the expansion of the sample with increase of temperature. There is agreement within 1 K between Eisenberg's determination of 263 K and that calculated from the equation given in Fig. 3 with $R = 1$, even though different routes were used for the preparation of the phosphoric acid samples. In spite of the complicated crystallisation behaviour reported for the metaphosphoric acids subject to different thermal treatments[1] it is clear that either dehydration of phosphoric acid at 300 °C or equilibration of a mixture of phosphorus pentoxide with water, yield products with the same glass transition temperature.

Caution is required in the application of the equation (Fig. 3) and it should not be used for values of $R < 1$. There is increasing cross linking as R is reduced below 1, because of the formation of trifunctional units through the elimination of water by condensation of hydroxyl groups on adjacent chains.

Glass transition temperatures are increased by cross linking but at present it is difficult to test relationships between glass transition temperatures and degree of cross linking. This is because reliable methods for the determination of the concentration of cross links may not be available[4]. Hence because of this increase in cross linking the use of the equation in the region $0 < R < 1$ is inappropriate. For compositions with $R > 4$, experimental determinations of T_g are required before it is possible to check on the applicability of this equation.

When a proton NMR spectrum has a narrow linewidth, $\delta H < 0.25$ gauss, there must be isotropic reorientation of the nuclei at a rate $> 10^4$ Hz, so that $\langle H_{loc} \rangle$ is effectively zero, and the measured line width is determined by the homogeneity of the applied magnetic field and other instrumental factors. When the signal is broad, $\delta H \sim 4-5$ gauss or more, then the protons are in relatively fixed positions. Thus, if a sample has a broad line it must be a solid. For these phosphoric acids the linewidth is broad, up to 5 gauss, even for the sample with $R \sim 4$ at $T < 200$ K. Thus this sample is a glass at temperatures < 200 K. While it is possible for an amorphous material to have molecular motion of various types at $T < T_g$, it is not possible for a sample to have a broad NMR line at $T > T_g$. Therefore, T_g for all these samples must be > 200 K. Kobeko's estimate of 152 K for the glass transition temperature of orthophosphoric acid is far too low.

The use of the definition $T_g = T_i$ (Fig. 2) together with application of our equation, allows estimation of glass transition temperatures in the composition range $1 \leqslant R \leqslant 4$. For orthophosphoric acid, $R = 3$, the predicted glass transition temperature is 229 ± 2 K.

Regenerative failure of double half limbs in *Notophthalmus viridescens*

IT HAS been proposed that positional information in epimorphic fields is specified in terms of polar coordinates[1], where one component of positional information is a value corresponding to position on a circle, and the other to position on a radius. In the newt limb, the circular sequence of positional values lies around the circumference and the radial sequence lies in the proximal–distal axis of the limb. French *et al.*[1] have proposed that various different regulative phenomena in such epimorphic fields as insect legs, insect imaginal disks, and amphibian limbs can be accounted for by two principles of cellular behaviour. The first of these is shortest intercalation, whereby any discontinuities in positional information are resolved by intercalation of missing positional values during growth. The second principle is that distal transformation can only take place from a complete set of positional values in the circular sequence. Unless a complete circle is either present at a site of amputation, or can be generated by intercalation from an incomplete circle, no regeneration (distal transformation) will occur. These principles have been used to account for the number, location, handedness and orientation of supernumerary regenerates produced after grafting experiments in amphibians[2] and insects[3]. The results reported here directly support the idea that a complete circle of positional values in the circular sequence is necessary for limb regeneration in adult newts.

Double half limbs were made in *Notophthalmus viridescens* as shown in Fig. 1. Controls were sham operated limbs in which either an anterior or a posterior half of an upper arm had been removed and replaced in normal orientation. All grafts healed into place rapidly and became fully vascularised by an average of 14 d after operation. The regenerative ability of the controls and the double half limbs was tested by amputating through the grafted region, close to its distal end, usually after 3–4 weeks, but sometimes after 8–9 weeks (eight double half limbs).

All 18 control limbs regenerated normally (Table 1 and Fig 2e), showing that the techniques used do not impair regenerative ability, and that an interval of 3–4 weeks between grafting and amputation is sufficient for restoration of an adequate nerve supply at the amputation plane. When double half limbs were amputated, however, regeneration either failed or was defective. The results were similar for both double anterior and double posterior limbs, and for limbs which were amputated 3–4 weeks and 8–9 weeks after grafting. Of 16 double anterior limbs tested (Table 1), none regenerated normally, and of 18 double posterior limbs,

Table 1 Regenerative ability

Limb type	Total	Defective or no regeneration	Normal regeneration
Control posterior	11	0	11
Control anterior	9	0	9
Double posterior	18	17	1
Double anterior	16	16	0
Half posterior	32	5	27
Half anterior	30	4	26

Fig. 1 Diagram of the grafting operation. *a*, Left and right limbs, cut away distally, to show the major anatomical features. The major muscles of the upper arm are the anconeus, coracobrachialis and humeroantebrachialis. A, Artery; N, nerve; V, vein. To make a double anterior limb, a 1.5-mm long section of the posterior half of a right upper arm was removed by making mid-dorsal and mid-ventral incisions, as well as proximal and distal incisions in the posterior half of the limb, down to the bone. The loosened posterior half was pulled away and discarded. An anterior half limb of matching dimensions from the left upper arm was grafted on to the right limb in place of the discarded posterior half. The graft was oriented normally with respect to its dorso–ventral and proximal–distal axes. Double posterior limbs were made by grafting the posterior half of the right upper arm in place of the anterior half of the left. *b* and *c*, Schematic representations of the operations to form double anterior and posterior limbs. Key positional values in the circular sequence are indicated by numbers from 0 to 12. Operations were performed using chloretone anaesthesia. In all cases, the mid-ventral nerves and artery were left undisturbed on the limb stump. All grafts were stained for 2 min in a 0.05% solution of methylene blue in Holtfreter solution[11] before grafting. Grafts were held in place with small pieces of damp lens paper, and the operated animals were kept cold (10 °C) for 2 d. Between the time that the animals were removed from the cold and the time that their limbs were amputated, they were kept at room temperature (20 °C). Thereafter they were maintained at 25 °C for the remainder of the experiment (2–2.5 months).
only one formed a normal distal regenerate. The range of skeletal structures formed by the double half limbs 2–2.5 months after amputation varied from little more than a cartilaginous cap on the cut end of the humerus (Fig. 2*c*) or a small separate cartilaginous nodule (Fig. 2*b*) to several small skeletal elements arranged in series (Fig. 2*a* and *d*). These results provide support for the hypothesis of French *et al.*[1] that a complete set of positional values in the circular sequence is necessary for distal transformation in amphibian limbs. The results of preliminary experiments performed on *Ambystoma tigrinum* by Stocum (personal communication) confirm this main result in another species of amphibian.

Previous experiments[4,5] provide further support for the complete circle rule in amphibian limbs. Limbs rendered incapable of regeneration by X irradiation could be caused to regenerate if they were provided with a normally oriented cuff of non-irradiated skin, that is, one containing a complete set of positional values in the circular sequence. It

was also shown, however, that a cuff of skin which was oriented so that only a single 'quality' (that is dorsal, ventral, anterior or posterior) was present at the amputation site could not cause X-irradiated limbs to regenerate. Although the amount of non-irradiated tissue available for regeneration was the same in both instances, regeneration occurred only when this tissue was oriented so as to produce a complete set of positional values in the circular sequence at the amputation site.

Further evidence for the relationship between a complete circle and normal distal transformation comes from the lateral supernumerary regenerates which sometimes formed in the grafting experiments (Fig. 2*d*). In 10 of 18 double posterior limbs and in one of the 16 double anterior limbs (but never in the control limbs), regenerative changes leading to the formation of a complete lateral supernumerary limb were initiated at the proximal graft–host junction when the limb was amputated through the distal region of the graft. A complete, lateral circle of positional values is
Fig. 2 Skeletal preparations of control and experimental limbs, prepared by the Victoria blue technique[12] 2–2.5 months after amputation. *a* and *b*, Double anterior limbs. *c* and *d*, Double posterior limbs, showing the spectrum of structures produced at the distal amputation site. In (*d*) a lateral supernumerary regenerate (arrow) has developed from the proximal graft–host junction. *e*, A control limb in which the posterior half of the upper arm had been removed and replaced.

created at this position in the experimental limbs (Fig. 3), with half of the values provided by the host and half by the graft. Preliminary evidence from similar grafts made in axolotls indicates that such supernumerary limbs contain cells of both host and graft origin (my unpublished results with Krasner).

The details of the mechanisms involved in distal transformation, and the need for a complete set of values in the circular sequence are unknown. In spite of their failure to complete distal transformation, in these experiments all double half limbs initiated regeneration. Except for one case, however, none proceeded beyond the stage of late bud[6] and the majority were arrested at earlier stages.

A possible alternative interpretation of the failure of double half limbs to regenerate normally is that they have an insufficient number of nerve fibres at the site of amputation. This explanation is untenable for several reasons. First, the major mid-ventral limb nerves were left intact in all cases (Fig. 1). Second, control limbs always regenerated normally. Third, doubling the interval between grafting and amputation from 3–4 weeks to 8–9 weeks, to allow even longer for innervation to occur, did not alter the regenerative performance of double half limbs. Finally, more evidence comes from a multiple grafting experiment in which a double anterior limb is made, left to become vascularised and innervated, then the original host anterior half is replaced by a grafted posterior half, to form a reversed but normal limb. When such limbs are amputated after an appropriate interval, regeneration of a disharmonic limb occurs as expected from the reversed but complete limb stump (my unpublished results). These preliminary results, in addition to the other evidence cited here, indi-

cate that the ability of double half limbs to become adequately innervated is not impaired, and that this alternative interpretation of the failure of double half limbs to regenerate can be rejected.
Fig. 3 Diagram of a double posterior limb stump indicating the complete circle of positional values at the proximal graft–host junction. The placement of positional values around the circumference is slightly non-uniform, as suggested by previous results and discussed in ref. 2. The graft is shown to be shorter than it actually is in order that the proximal graft–host junction can be clearly visualised.

In these experiments the regenerative ability of half limbs was also examined (Table 1). In each animal in which one double half limb was produced, the limb from which the graft was taken remained as a half limb, either half anterior or half posterior. These half limbs, as well as half limbs produced on both forelimbs of the same animal were either amputated immediately through the most distal portion of the half limb, or amputated 3–4 weeks later. Most of these limbs developed complete and normal regenerates, thus confirming earlier findings that half limbs can regenerate normally[7,8] or relatively normally[9]. The initial outgrowth did not arise at the most distal cut end of the half limb, but was eccentrically located towards the distal end of the lateral wound edge. During the later stages of regeneration, the regenerate became more symmetrically disposed until by the stage of late digits, little or no asymmetry could be detected. A tentative interpretation of this finding is that the eccentric location of the initial outgrowth is the position on the wound surface at which cells comprising a complete circle of positional values come together during wound healing from the proximal and distal half limb stumps. This possibility is being investigated.

The many similarities between the regulative behaviour of insect and amphibian limbs have led to the hypothesis that the mechanisms of pattern regulation in these distantly related organisms are the same[1]. This idea is strengthened by the similarity of the results reported here to those reported by Bohn[10] with double dorsal and double ventral cockroach legs.

I thank Julie Van Houten for pilot experiments on this project, Warren Fox for assistance and Carol Wilde for art work. This research was supported by a grant from the NIH.

Detection and repair of single-strand breaks in nuclear DNA

DIRECTLY or indirectly phosphodiester bonds in DNA are broken when living cells are irradiated by ionising radiations or ultraviolet light. There are various sophisticated techniques for monitoring radiation damage[1–6]. We describe here how radiation damage in DNA and its repair can be detected simply in the white cells of human blood. The method is very sensitive and should prove useful in screening populations for abnormal repair mechanisms. As there is also great interest in methods for detecting environmental agents that damage DNA[2,7], we have applied the method to detect the damage caused by mitomycin C.

We have described our technique for detecting the damage caused to the nuclear DNA of HeLa cells by very low doses of γ rays and also for monitoring the repair of this damage[8,9]. When cells are lysed in the presence of non-ionic detergents and high salt concentrations, structures resembling nuclei—called nucleoids—are released. These nucleoids contain nearly all nuclear RNA and DNA, but are depleted of nuclear proteins[10]. Their DNA is supercoiled and compact so that the nucleoids sediment more rapidly in sucrose gradients than their γ-irradiated counterparts which contain extended DNA with single-strand breaks or nicks. Repair of the breaks restores the DNA to its original conformation and re-establishes the normal sedimentation rate. We monitor DNA integrity by measuring the distance sedimented by nucleoids in sucrose gradients.

Nucleoids are released immediately on addition of white blood cells to a lysis mixture containing the non-ionic detergent Triton X-100 and 1.95 M NaCl. The effects of the intercalating dye, ethidium bromide (EB), on the sedimentation of nucleoids derived from white blood cells was studied by spinning the nucleoids through sucrose gradients containing 1.95 M NaCl and different concentrations of the dye (Fig. 1). The distance travelled by the nucleoids is expressed as a ratio relative to that travelled by unirradiated nucleoids sedimenting in the same conditions but in the
Fig. 1 Effect of EB on the sedimentation of nucleoids from human white blood cells. The distance sedimented by nucleoids in gradients containing different concentrations of EB is expressed as a ratio relative to that of unirradiated nucleoids sedimenting in the absence of EB. ●, Unirradiated nucleoids; ○, nucleoids γ irradiated (960 rad, 120 rad min^{-1}) after addition of cells to the lysis mixture[8]; △, unirradiated nucleoids from a patient with xeroderma pigmentosum. Error bars give the standard error of the mean. Human white cells were obtained from peripheral blood[17] and cultured in RPMI 1640 medium supplemented with 20% foetal calf serum (Flow Laboratories). Between 1 and 5% of the cells prepared in this way are red cells, the remainder are almost all lymphocytes. The results obtained with blood from four normal males and two females were pooled. In some cases white cells stored in medium on ice for 24 h were used; the sedimentation properties of nucleoids prepared from such cells were similar to those obtained from freshly isolated cells. Samples of 50 μl of a suspension containing between 2 and 5×10^5 cells in phosphate-buffered saline (PBS) were layered on 150 μl of a lysis mixture floating on top of "isokinetic" sucrose gradients[8,10]. Gradients (15–30% sucrose, 4.6 ml, pH 8.0) contained 1.95 M sodium chloride, 0.01 M Tris, 0.001 M EDTA in addition to various concentrations of EB. The lysis mixture contained sodium chloride, EDTA, Tris and Triton X-100 in amounts which, on addition of 1 volume of PBS containing cells to 3 volumes of the mixture, gave final concentrations of the constituents of 1.95 M, 0.1 M, 2 mM and 0.5% respectively. (For the purpose of calculating the final concentration of sodium chloride, the contribution of the PBS is neglected). Fifteen minutes after the addition of the cells to the lysis mixture, gradients were spun at 30,000 r.p.m. for 25 min at 20 °C in the SW50.1 rotor in a Beckman L2-65b ultracentrifuge. After the gradients had been spun, the position of the nucleoids in the gradient was determined by their absorbance at 254 nm. One gradient of the six spun in the rotor served as a reference; the distance travelled by nucleoids in other tubes is expressed relative to the distance sedimented by nucleoids in the reference tube[8].

absence of EB. As the concentration of EB in the gradient is increased, the distance travelled by nucleoids falls to a minimum and then rises again. γ Irradiation reduces the sedimentation rate of the nucleoids and abolishes the biphasic response to EB. The shape of a similar curve obtained with HeLa nucleoids is discussed elsewhere[9]. As the sedimentation rate of supercoiled DNA varies in this characteristic biphasic manner[11], we conclude that nucleoid DNA is supercoiled. Irradiation introduces single-strand breaks into the DNA so that supercoils are lost.
Fig. 2 Effect of incubation of white blood cells after γ irradiation on nucleoid sedimentation. The distance sedimented by nucleoids from irradiated cells in gradients lacking EB is expressed as a ratio relative to that of nucleoids from unirradiated cells which had been treated similarly. White cells (2 × 10⁴ per ml in medium) were irradiated (960 rad)[9], and incubated for different times at 37 or 4 °C. They were then added to 10 volumes of ice-cold PBS, pelleted and resuspended in ice-cold PBS. Samples of 50 µl were applied to gradients which were then spun and analysed as described in the legend to Fig. 1. Error bars give the standard error of the mean. Normal white blood cells, irradiated and incubated at 37 °C (●) or 4 °C (○). White cells from a patient with xeroderma pigmentosum, irradiated and incubated at 37 °C (■).

Repair of the damage caused by γ irradiation was studied by irradiating white blood cells (960 rad) and then incubating them for different periods before applying them to gradients lacking EB and then measuring the sedimentation rate of the nucleoids. (A dose of 960 rad reduces the cloning efficiency of HeLa cells by 99% (ref. 8). Incubation at 37 °C after irradiation, but not at 4 °C, increased the sedimentation rate of the nucleoids (Fig. 2). After 5 h, the sedimentation rate had been restored almost to that of un-irradiated nucleoids, and the nucleoids from the irradiated cells had regained their biphasic response to EB (Table 1).

These techniques have been extended to include measurements on the effects of ultraviolet light. Repair of damage induced by ultraviolet light involves cutting one strand of the DNA duplex ("incision"), removal of the principal photoproduct, the thymine dimer ("excision"), synthesis of DNA complementary to the unaffected strand and "ligation" of the final phosphodiester bond to restore the intact duplex[9]. HeLa cells were irradiated (25 erg mm⁻²) and incubated for different times at 37 °C before the sedimentation rate of nucleoids isolated from them was measured in gradients lacking EB (Fig. 3a). (A dose of 25 erg mm⁻² reduces the cloning efficiency of HeLa cells by 24% (our unpublished results).) Irradiation without subsequent incubation at 37 °C reduces the rate of sedimentation. This probably results from the single-strand breaks induced by the highly active incision enzymes of HeLa cells during the time taken to concentrate the cells before they are lysed. (Although the formation of a thymine dimer in DNA unwinds the double helix by 5–6° (ref. 12), the sedimentation rate is unlikely to be reduced by such unwinding

in the absence of strand scission because irradiation of isolated nucleoids with high doses of ultraviolet light does not alter the sedimentation rate (our unpublished results).) Incubation of the cells at 37 °C for 5 min after irradiation reduced the rate of sedimentation of the nucleoids further, whereas incubation periods greater than 20 min increased the distance sedimented until it became indistinguishable from that of the unirradiated controls. We conclude that after irradiation, incision initially leads to a partial loss of supercoils in nucleoid DNA, but then ligation restores supercoiling (Fig. 3a).

A measure of the damage caused by different doses of ultraviolet light is given by the distance sedimented in the absence of EB by nucleoids after the irradiated cells had been incubated for 5 min at 37 °C to maximise the number of strand breaks (Fig. 4). As radiation dose increased, the distance sedimented decreased progressively.

The damage caused by ultraviolet light is repaired much more slowly in white blood cells than in HeLa cells. Strand breakage and loss of supercoiling were maximal 2 h after irradiation. The normal supercoiled configuration was not fully recovered after 15.5 h (Fig. 3b and Table 1). There was
Fig. 3 Effect on nucleoid sedimentation of incubating (a) HeLa cells and (b) human white blood cells at 37 °C after irradiation with ultraviolet light. a, Human HeLa cells were grown in suspension[9]. 0 5 ml of cells (2 × 10⁴ per ml) in ice-cold medium in a Petri dish were irradiated (25 erg mm⁻¹, 5 erg mm⁻¹ s⁻¹) with ultraviolet light while the Petri dish was shaken vigorously. The source of ultraviolet light was a Sylvania germicidal tube (G 15T8). Doses were measured with an ultraviolet meter[14]. After irradiation, cells were mixed with 4.5 ml of medium at 37 °C and incubated in the dark at 37 °C. At the end of incubation the cells were mixed with 9 volumes of ice-cold PBS, pelleted and resuspended in ice-cold PBS. Samples of 50 µl of the cell suspension were applied to sucrose gradients lacking EB. Gradients were spun at 5,000 r.p.m. for 50 min and analysed as described in the legend to Fig. 1. The distance sedimented by nucleoids derived from irradiated cells is expressed as a ratio relative to the distance sedimented by nucleoids derived from cells treated similarly but which had not been irradiated. Error bars give the standard error of the mean. b, The experiments with white blood cells were similar to those with HeLa cells except that media and spinning conditions were different (see legend to Fig. 1). ●, Normal white blood cells, irradiated and incubated at 37 °C; ○, normal white blood cells, irradiated and incubated at 4 °C; ■, white blood cells from a patient with xeroderma pigmentosum, irradiated and incubated at 37 °C.

Table 1 Effect of different treatments on supercoiling in the nucleoids from white blood cells

Treatment	Relative distance sedimented by nucleoids in the presence of EB			
	$0 \, \mu g \, ml^{-1}$	$2 \, \mu g \, ml^{-1}$	$4 \, \mu g \, ml^{-1}$	$16 \, \mu g \, ml^{-1}$
Untreated	1.0	0.53	0.59	0.73
4-h incubation at 37 °C after γ irradiation (960 rad)	0.82	0.53	0.66	0.65
2-h incubation at 37 °C after ultraviolet irradiation (25 erg mm^{-2})	0.39	0.39	—	0.35
15.5-h incubation at 37 °C after ultraviolet irradiation (25 erg mm^{-2})	0.84	0.58	—	0.68

Nucleoids obtained from cells treated in different ways were spun in gradients containing different concentrations of EB. The distance sedimented by nucleoids from treated cells is expressed as a ratio relative to that of nucleoids from untreated cells sedimenting in the absence of ethidium. The conditions used for the untreated cells, and cells irradiated with γ rays or ultraviolet light are described in the legends to Figs 1, 2 and 3, respectively.

little change in the sedimentation rate of nucleoids when the irradiated cells were incubated at 4 °C (Fig. 3*b*).

Cells from patients with the autosomal recessive disease, xeroderma pigmentosum can repair the damage caused by ionising radiation but cannot effectively repair DNA damaged by ultraviolet light. Some forms of this disease are thought to be characterised by deficiency in "incision" activity[5]. Nucleoids prepared from the white cells of our patient sedimented in gradients containing EB exactly as the nucleoids from normal cells (Fig. 1). In the absence of EB the sedimentation behaviour of nucleoids prepared from γ-irradiated cells was also indistinguishable from that of nucleoids prepared from normal cells that had been irradiated (Fig. 2): the patient's cells could thus repair γ-ray damage. On the other hand, irradiation with ultraviolet light affected normal cells and those of the patient differently (Fig. 3*b*). When the patient's cells were irradiated with ultraviolet light and incubated at 37 °C the sedimentation rate of the nucleoids in the absence of EB was not reduced as much as that of controls : the patient's cells were unable to "incise" normally and the nucleoids retained supercoils and sedimented rapidly.

Mitomycin C is a carcinogen[7]. After activation by cellular enzymes it cross links DNA strands without breaking them. Strands are broken only when the damaged region is removed by repair enzymes[13]. We investigated the effects
Fig. 4 Effect of different doses of ultraviolet radiation on the sedimentation of HeLa nucleoids. HeLa cells were irradiated for 5 s with different doses of ultraviolet light, incubated for 5 min at 37 °C, applied to sucrose gradients lacking EB and the gradients were spun and analysed (see legend to Fig. 3). The distance sedimented by nucleoids derived from irradiated cells is expressed as a ratio relative to the distance sedimented by nucleoids derived from cells which had been treated similarly but which had not been irradiated. Error bars, s.e.m.

of mitomycin C on the integrity of DNA by incubating white cells at 37 °C for 2 h in different concentrations of the drug, lysing the cells, and determining the rate of sedimentation of the nucleoids in the absence of EB (Fig. 5). Low concentrations of the drug had no effect on the distance sedimented, higher concentrations reduced it. At the high concentrations, strand breakage caused loss of supercoiling and slow sedimentation. The effects of lower concentrations can be detected by incubating the cells with the drug for longer periods (our unpublished results). If, after a 2-h exposure to the drug, the cells were washed and incubated

in its absence at 37 °C for 15.5 h, faster sedimentation was restored, repair of the damage restored normal supercoiling.

We have made nucleoids containing superhelical DNA from a wide range of cells (fibroblasts, lymphoblasts, erythroblasts, teratocarcinoma and epithelial cells of men, mice, birds, amphibians and insects (ref. 9 and our unpublished observations)), so that these methods for detecting single-strand breaks in DNA should be applicable to most cells.
Fig. 5 Effect of mitomycin C treatment of white cells on the sedimentation of nucleoids in gradients lacking EB. White cells were incubated for 2 h at 37 °C (see legend to Fig. 1) in the presence of different concentrations of mitomycin C (Boehringer). Some cells were then collected and applied to gradients immediately and the gradients were spun and analysed (see legend to Fig. 1). Other cells were washed twice with medium, resuspended at 2×10^6 per ml in medium lacking mitomycin C and incubated a further 15.5 h at 37 °C. They were then collected and treated as the others.. The distance sedimented by nucleoids derived from cells treated with mitomycin C is expressed as a ratio relative to the distance sedimented by those derived from untreated cells. Error bars, s.e.m. ●, Cells incubated for 2 h in the presence of mitomycin C. ○, Cells incubated for 2 h in the presence of mitomycin C, washed and then incubated for a further 15.5 h at 37 °C.

Using white cells obtained from human blood taken in the morning, we can assess by the evening whether repair of damaged DNA in the cells is normal. While doses of 960 rad (γ rays) or 25 erg mm^{-2} (ultraviolet light) produce the large effects described in these experiments, much lower doses (that is, 12 rad and 5 erg mm^{-2}) can be detected. The method should therefore be particularly well suited to the rapid screening of patients for deficiencies in the mechanisms that repair radiation damage.

Many carcinogens and mutagens break phosphodiester bonds in cellular DNA either directly or indirectly after enzyme action. Breakage, which can be demonstrated by

conventional physical techniques[14] probably increases repair synthesis[15] and recombination[3,16]. Agents that break DNA can be detected in nucleoids with the sensitivity, rapidity and economy usually associated with the use of bacteria[7]. There may well be advantages in using human cells in any screening method for detecting potential human carcinogens.

We thank Dr F. Giannelli for help and for white blood cells from a patient with xeroderma pigmentosum, and Professor H. Harris for support and encouragement. We thank the SRC and the CRC for support.

Evidence of a thymic abnormality in murine muscular dystrophy

THE involvement of the thymus in muscular, neuromuscular and neurological disorders is well documented[1–4]. In spite of the extensive study made of the thymus in myasthenia gravis, which, as a neuromuscular disorder with clinical symptoms of muscular weakness, shares some similarities with muscular dystrophy, the state and function of the thymus in muscular dystrophy has been ignored. The poor health and susceptibility to infection of dystrophic mice have frequently been observed. These observations and the similarities between dystrophic wasting and that seen in mice thymectomised pre- or neonatally[4], led us to the conclusion that an investigation into the status of the thymus in murine muscular dystrophy was warranted. We have found that the thymuses of dystrophic mice exhibit changes in the age-dependent variation in thymic weight, together with aberrations in cellular morphology indicative of altered secretory activity.

Male and female dystrophic mice of the Bar Harbor 129/ReJ strain were killed by cervical dislocation at various ages, their thymuses, spleens and elbow lymph nodes removed, dissected free of fat and connective tissue, weighed and fixed in 10% formol-saline or methanol. The thymuses, spleens and lymph nodes from clinically normal littermates, and also from a non-dystrophic strain of mice (CBA), were used for comparison. The organs were paraffin embedded and subjected to routine haematoxylin–eosin staining procedures. Unna–Pappenheim staining was also used[5]. The histology of random single sections of these organs was then compared.

For an initial indication of thymic status, the thymus weights of normal and dystrophic mice were compared. It is not possible to compare thymic indices in these animals because of the selective wasting of hind limb muscle in the dystrophic mouse. Generally, mouse thymuses have

been found to decline in weight from 4 to 12 weeks of age; the thymuses of the normal littermates followed this trend. In dystrophic mice, the thymic weights were at first much lower, but then increased with age, reaching a maximum at approximately 9 weeks of age, at a weight comparable to that of the normal mouse at 4–6 weeks of age. The thymic weights of the dystrophic mice then slowly declined to a level approaching that of their normal littermates at 12 weeks of age (Fig. 1). In all strains of mice so far studied, there has been to our knowledge, no report of a similar weight gain to 9 weeks of age, the predominant pattern being an increase in weight to 4 weeks of age,
Fig. 1 Thymus weight as a function of age in normal and dystrophic mice. Thymus weight (mg)±s.d. Normal mice, 4–7 animals per group. Dystrophic mice, 2–6 animals per group.

followed by a gradual, but definite, decrease in weight which continues throughout the life span of the animal[7].

This anomaly led us to consider the histology of the thymus of dystrophic mice. As shown in Fig. 2, this also differed dramatically from the normal. While the normal littermates showed no abnormalities of basic thymic morphology, a number of the dystrophic animals studied exhibited remarkable alterations of thymic cellular composition. In the main, this consisted of a depletion, and in some cases, total absence of lymphocytes from lobules of the thymus, these being replaced by epithelial cells which showed very marked signs of secretory activity[4]. In extreme cases, the epithelial cells had formed themselves into classical, though duct-less acini, surrounding a material which did not stain in the conditions used. These drastic changes in thymic composition were found in young (3–8 weeks of age) dystrophic mice which were severely affected by the disease, as evidenced by the degree of disability. In older animals, and those less severely affected, the thymus showed less dramatic changes. These consisted of an apparent relative increase in medullary area over cortical area and a loss of distinction of the cortico–medullary junction. The change in the ratio of medulla to cortex could be due to an increase in medullary tissue or a decrease in the number of lymphocytes populating the
Fig. 2 Histology of thymuses from normal and dystrophic mice. *a*, Thymus from clinically normal littermate. The cortico–medullary junction is distinct; few epithelial cells can be detected in the cortex which is tightly packed with lymphocytes. Haemotoxylin and eosin, ×10.4. *b*, Thymus from severely affected dystrophic mouse. The three lobules shown were enclosed by a continuous capsule of thymic epithelium. The lobule on the left most closely resembles the normal state, but even here, patches of lighter staining cells can be seen in the outer cortex. The lobule on the right represents an intermediary stage in which the loss of definition of the cortico–medullary junction, the depletion of the lymphocytes present in the lobule, and the apparent increase in the number of epithelial cells, was the earliest and most consistent observation. The centre lobule shows the most extreme degree of alteration, having no resemblance to the normal thymus. The nuclei of what are presumed to be epithelial cells because of the presence of cytoplasm around the nuclei form a rim around an accumulation of poorly staining material, the chemical nature of which is unknown. Haemotoxylin and eosin, ×10.4.

cortex. As the packing of lymphocytes in the cortex was noticeably less dense, the latter explanation seems more probable. The cortico–medullary junction, which is normally quite distinct, was indefinite in dystrophic mice, the change from medulla to cortex taking place over a much larger area than is seen in the normal littermates. In some thymuses from dystrophic mice an infiltration of epithelial cells from the outer rim of the cortex, into the cortex, was also seen. The main changes seen in the thymuses in this study are summarised in Table 1.

As all these findings indicated a loss or lack of lymphocytes in the thymus of dystrophic mice, the spleen and lymph nodes were investigated as possible recruiting areas for the missing lymphocytes. Dystrophic spleen weights were found to differ from those of normal mice, the spleens of dystrophic mice being consistently smaller at all ages than those of their normal littermates (Fig. 3). It was also noted that while spleen weights of normal mice generally exhibited a certain variability, reflecting the ability of the

individual animals to respond to infectious agents and other stimulants of the immune system (splenomegaly), the spleen weights of the dystrophic mice were relatively constant. Investigation of splenic histology did not reveal any gross differences between normal and dystrophic mice. It was, however, noted that no germinal centres, as detected by Unna–Pappenheim staining, were seen in the spleens of dystrophic mice, although they were often found in the spleens of normal animals. The lymph nodes of dystrophic animals seemed to contain fewer lymphocytes and relatively more endothelial cells than the lymph nodes of normal animals.

These observations and the peculiarities of thymic weight and thymic histology all indicate a possible defect in function of the immune system in dystrophic mice. The altered morphology of the thymuses of dystrophic mice indicate an abnormal secretory activity of the epithelial cells of the thymus. These cells have been implicated as the site of synthesis and secretion of thymus hormones in normal mice[8,9]. A wide variety of actions have been ascribed to thymic hormones; notably, these include both potentiating and inhibitory actions on all immune functions, the capability of interacting with a variety of other endocrine hormones, and hence actions on growth, muscle regeneration and the capacity of the animal to respond to disease[10]. If, as the evidence suggests, there is a defect somewhere in the system of thymic hormones and/or their actions, this
Fig. 3 Spleen weight as a function of age in normal and dystrophic mice. Spleen weight (mg)±s.d. Normal mice, 4–7 animals per group. Dystrophic mice, 4 animals per group. The large variation in spleen weight of normal mice observed at 8.5 weeks of age is interpreted as a reflection of the capacity of these mice to undergo splenomegaly (see text). □, normal; ■, dystrophic.

could explain a well known, but generally ignored, characteristic of murine muscular dystrophy. The disease has a random clinical onset and remarkably variable progression, some animals dying at 3 weeks of age, others surviving to 6 months. If this disease has an hormonal basis, then individual animals would be expected to have different capacities to compensate for an hormonal excess or insufficiency, inactivity or hyper-reactivity, by alteration of other hormones with which the affected hormone interacts. The intricacies of such interaction and compensation between endocrine hormones, and the variation between individuals has been reviewed[11]. Furthermore, the finding that the thymus weights of dystrophic mice follow an age-pattern different from that of normal mice, regardless of severity of disease, or extent of thymic abnormality, suggests that the thymus is abnormal in all dystrophic mice. The effect and extent of this abnormality may be defined by a more complex system, which is individually determined. In this connection, it is worth noting that, as remarked previously, gross signs of epithelial secretion in the thymus were detected only in those dystrophic animals severely affected early in life. In particular, the thymuses of two 3-week-old mice which were close to death from the dystrophic process, were totally epithelial in nature and with a marked degree of secretory activity evident.

Table 1 Histological features of thymuses from normal and dystrophic mice

| | | | Histological features | |
	No. of mice	% normal	% without distinct cortico–medullary junction	% showing signs of epithelial secretion
+/?	40	90	10	5
dy/dy	45	4	96	29
CBA	10	100	0	0

The percentage of abnormalities seen in clinically normal animals (+/?) may be explained by the uncertainty inherent in selecting as normal all animals which do not show overt clinical symptoms of dystrophy. It is possible that in doing this, animals which are dystrophic but have not yet developed the clinical symptons, may be classified as normal. It is for this reason that the CBA mice were included in this study. Further investigations are being made on the thymus of the homozygous normal Bar Harbor 129/ReJ strain of mice.

The effect of the thymus on immune mechanisms is most marked in mice in neonatal and early postnatal life (up to 4 weeks of age); thereafter the influence of the thymus on immunological capacity declines. Also, the signs of epithelial secretion noted in the thymuses of dystrophic mice at various ages after 2 weeks of age, are similar to those found by Clark in normal mice from birth up to an age of 2 weeks[6].

The alteration of thymic weights have been independently confirmed by D. F. Horrobin and R. A. Karmali (see following paper), who found alterations in the responses of thymuses from dystrophic animals to prolactin, and to the suppression of prolactin secretion.

On the basis of these observations, it is postulated that the thymus in murine muscular dystrophy is functionally altered, and that this alteration probably results in the abnormal secretion of one or more thymic hormones. Whether this altered secretion is due to a malfunction within the thymus itself or to a disorder of a system interacting with the thymus, is not known. This and many other possible avenues are yet to be investigated. Further investigation of the thymic abnormality of dystrophic mice, including periodic acid–Schiff staining and ultrastructural studies, are currently underway.

Abnormalities of thymus growth in dystrophic mice

IN spite of the attention paid to the relationship between myasthenia gravis and the thymus, little work has been done on the thymus in muscular dystrophy. Walker[1] found that mouse dystrophy was not alleviated by neonatal thymectomy and Matheson[2] provided evidence against the idea that muscular dystrophy might be a lymphocyte-mediated autoimmune disease. It therefore seems unlikely that overactivity of lymphoid function of the thymus has any role in muscular dystrophy: the possible role of a thymic deficiency has not been considered. Our interest was aroused when we noticed that in certain superficial ways dystrophic mice of the Bar Harbor 129 strain[3–5] appear similar to mice which have been neonatally thymectomised. Their growth is stunted to a very variable degree, their coat quality is poor and they are liable to die suddenly for no very obvious reason. We now present evidence for an abnormality of thymus growth in these animals.

Initially we simply compared body and thymus weights in untreated 4-week and 12-week-old mice of the Swiss and Bar Harbor 129/ReJ strains. At 4 weeks, 1 week after weaning, it is usually possible to tell by observation whether a 129 animal is dystrophic (dy/dy) or phenotypically normal (+/+ or +/dy). The presence or absence of dystrophy was verified by muscle histology. The results are shown in Table 1. There were approximately equal numbers of each sex in each group and no sex differences were noted. At both 4 and 12 weeks the Swiss mice were significantly larger than phenotypically normal 129 mice (P<0.01)—which in turn were larger than the dystrophic mice. At 4 weeks there were no differences in absolute thymus weights between the Swiss and normal 129 mice but in the dystrophic mice the glands were very much smaller (P<0.001). At 12 weeks the normal reduction in thymus weight was well advanced in the Swiss mice but less so in the normal 129s. In the dystrophic animals thymus weight was actually greater than at 4 weeks (P<0.01). Because of the known effects of adrenal steroids on the thymus, in some of the dystrophic and phenotypically normal 4-week-old animals, we measured adrenal weights as well. In the normals mean weight of the adrenals was 3.4±0.5 (s.e.m.) mg and in the dystrophics it was 1.6±0.3 mg. Adrenal/body weight ratio

Table 1 Body and thymus weights and thymus/body weight ratios in Swiss mice and in dystrophic and phenotypically normal animals of the Bar Harbor 129 strain.

At 4 weeks of age	Swiss	Normal 129	Dystrophic 129
Number	16	8	8
Body weight (g)	21.4±1.36	17.3±0.76	9.3±1.9
Thymus weight (mg)	73.0±5.5	72.2±4.3	3.7±1.2
Thymus/body weight ratio (×10⁻²)	3.5±0.3	4.2±0.1	0.37±0.19
At 12 weeks of age	Swiss	Normal 129	Dystrophic 129
Number	16	8	8
Body weight (g)	32.4±0.9	26.2±0.82	16.5±1.1
Thymus weight (mg)	18.0±1.3	32.6±2.0	19.4±3.3
Thymus/body weight ratio (×10⁻²)	0.56±0.03	1.25±0.08	1.20±0.28

Results are shown as means ± s.e.m.

in the normals was 3.0×10^{-4} and in the dystrophics 3.1×10^{-4}. Adrenal weight is therefore a normal proportion of body weight in the dystrophic animals and it is unlikely that the thymus atrophy is caused by adrenal hyperactivity.

We then investigated the possibility that thymus growth might be affected at an earlier stage in the dystrophic animals. Three litters were killed between 15 and 20 d *post partum* before weaning. Dystrophic animals were identified by muscle histology. Thymus/body weight ratio in the normal 129s was 3.9×10^{-3} and in the dystrophics 2.3×10^{-3}. Thus the thymus was lower in weight at this stage but the severe reduction noted in the dystrophics one week after weaning was not found.

This pattern is similar to the situation in growth hormone and prolactin-deficient dwarf mice[6-8]. In these animals thymus growth is normal until weaning, apparently being maintained by a factor in the milk. On weaning rapid thymus atrophy occurs. This can be reduced or prevented by treatment with exogenous growth hormone or prolactin. Prolactin is known to be present in rodent milk[9] and it is possible that this is the necessary factor. Quite independently, de Kretser and Livett[10] in Melbourne have made similar observations on thymus growth in dystrophic mice. The interpretation of our common findings must obviously be uncertain at this stage although our own hypothesis is that both muscle and thymus are damaged by the basic genetic defect but that the clinical expression of the genetic defect in the muscles may depend on some of the consequences of thymus damage.

This work was carried out partly at the University of Newcastle upon Tyne, UK. We thank the North of England Cancer Campaign, the UK Muscular Dystrophy Association and the Quebec Medical Research Council for financial support, and Professor W. G. Bradley and the Staff of the Muscular Dystrophy Laboratories, Newcastle General Hospital, for the Bar Harbor 129 mice, and for much advice.

Foetoneonatal oestradiol-binding protein in mouse brain cytosol is α foetoprotein

BRAIN cytosol from foetal and neonatal rodents contains high concentrations of an oestradiol-binding protein (foetoneonatal oestradiol-binding protein or FEBP) with properties distinctly different from those of adult oestrogen receptors with respect to sedimentation rate, binding specificity and affinity for oestradiol[1-3]; FEBP declines to undetectable levels by about 22 d in rat brain cytosol[1,3]. Sexual differentiation of the rodent brain, which normally occurs under the influence of testicular secretions between birth and about 10 d, can also be brought about by injection of oestradiol benzoate into neonatal female or castrated male rodents[4]. This observation has led to the idea that FEBP protects the developing brain against the effects of maternal oestrogens[5]. It has been suggested that FEBP in rats is α foetoprotein (AFP)[5], a circulating foetal protein known to bind oestradiol[6-8]. Here we present evidence which points strongly to the identity of mouse FEBP and AFP This includes a comparison of the binding properties of FEBP with those of purified mouse AFP, correlation of the postnatal disappearance of FEBP with measurements of AFP in brain cytosol and removal of oestradiol-binding activity from brain cytosol using anti-mouse AFP antibodies.

Cytosol—prepared from a homogenate of pooled brains from neonatal mice by centrifugation at 216,000g—or mouse AFP—purified by immunoadsorbents[10,11]—was incubated for 2 h at 0 °C with 5×10^{-9} M ³H-oestradiol and centrifuged on glycerol gradients (Fig. 1). The sedimentation coefficients of the peaks of ³H-radioactivity were estimated to be 4.6±0.03S for FEBP (mean ±s.e. of nine determinations involving five preparations from 1-5-d-old mice) and 4.7±0.02S for AFP (mean ±s.e. of 13 determinations on four different AFP preparations). This slight difference in the sedimentation rates of AFP and FEBP could be due to a change that occurred in the AFP molecule as a result of the purification; this was supported by the observation that an AFP preparation purified from brain cytosol gave an S value (4.7 S) comparable with that of the other purified AFP preparations. Figure 1 also shows that excess unlabelled oestradiol (10^{-6} M) decreased binding of ³H-oestradiol to both FEBP and AFP by 80–90%. Diethylstilbestrol (DES), a potent synthetic oestrogen, at 10^{-5} M, had no effect on oestradiol binding to FEBP, in agreement with results reported for rat FEBP[1,3]; 103% (mean of four determinations) of the ³H-c.p.m. found in this peak in the absence of DES was bound in its presence. DES competed slightly, however, with ³H-oestradiol for binding to purified mouse AFP (17%, mean of four determinations); ³H-DES has also been reported to bind to purified rat AFP[6]. The apparent difference in sensitivity to DES competition between FEBP and AFP was abolished when purified AFP
Fig. 1 Glycerol gradient centrifugation of 5-d brain cytosol and mouse AFP incubated with ^{3}H-oestradiol and ^{3}H-testosterone. Cytosol was prepared from pooled brains of 5-d-old female mice or from 3–5-month-old adult mice in TEM (0.01 M Tris, pH 6.7, at 25 °C; 0.0015 M EDTA; 0.002 M β-mercaptoethanol) by centrifugation for 1 h at 216,000g as described before[13]. Mouse AFP, purified by immunoadsorbents[10,11], was dissolved in TEM. Samples of 0.4 ml of 5-d cytosol (4.7 mg per ml of protein) (a), of AFP (18 μg ml⁻¹) (b), or of AFP (18 μg ml⁻¹) in adult cytosol (6.8 mg per ml of protein) (c) were incubated with 5 × 10⁻⁹ M [3]H-17β-6,7-oestradiol (47.9 Ci mmol⁻¹) in the absence (●) or presence of unlabelled oestradiol at 10⁻⁶ M (○) or DES at 10⁻⁶ M (△), and with 5 × 10⁻⁹ M [3]H-1α,2α-testosterone (59 Ci mmol⁻¹) (×) for 2 h at 0 °C. Samples were layered on 5–35% linear glycerol gradients in TEM and centrifuged in the SW 50.1 rotor at 216,000g for 16 h at 2 °C. The scale on the left of (b) refers to the gradients containing ^{3}H-oestradiol, while that on the right refers to the gradient containing ^{3}H-testosterone. The arrow indicates the position of bacterial alkaline phosphatase added as an internal sedimentation marker (6.2S, see ref. 13). The direction of sedimentation was from right to left.

was incubated with ^{3}H-oestradiol in the presence of brain cytosol from adult mice (which contains no detectable FEBP). DES no longer displaced any radioactivity from the AFP peak (Fig. 1); in two such experiments, 104% and 109% of the ^{3}H-c.p.m. were recovered in the AFP peak in the presence of DES. There was no indication of binding of ^{3}H-testosterone to either FEBP or mouse AFP (Fig. 1).

Binding parameters for the reaction of brain cytosol or mouse AFP with ^{3}H-oestradiol were obtained by Scatchard[12] analysis after equilibrium dialysis. This method was chosen since we[13] and others[14] have observed that there is a rapid dissociation of the FEBP-oestradiol complex in non-equilibrium conditions. The mean dissociation constants (k_D) from two experiments were 2.3 × 10⁻⁸ M (brain FEBP) and 2.4 × 10⁻⁸ M (mouse AFP); these are essentially the same as published values for rat brain FEBP[1] and purified rat AFP[9].

AFP was demonstrable in brain cytosol from immature mice by immunodiffusion or radioimmunoassay[10]. Cytosol from 1-, 4–5-, 9–10- and 20–22-d-old mice gave AFP concentrations (mean ±s.e.) of 7.0±0.8 μg (seven determinations), 1.5±0.2 μg (three determinations), 0.24±0.02 μg

Fig. 2 Scatchard plots representing binding of ^{3}H-oestradiol by 4-d brain cytosol (a) and mouse AFP (b). Samples of 0.35 ml of brain cytosol from 4-d-old male mice (11 mg per ml of protein) or of AFP (17 μg ml⁻¹) were dialysed against 10 ml TEM containing various concentrations of ^{3}H-oestradiol (OII) (2 × 10⁻⁹–1 × 10⁻⁷ M) for 24 h at 4 °C. Triplicate samples of the inner and outer solutions were removed for counting. Bound radioactivity was determined from the difference between the radioactivity inside the dialysis bags and that outside.

(three determinations), and <2 ng (undetectable level) per mg of protein, respectively. There were 0.7–0.8 mol of oestradiol bound per mol of mouse AFP (molecular weight 74,000 (ref. 10)), and the binding capacity of brain cytosol from 4-d-old mice was about 25 pmol per mg of protein (Fig. 2). Assuming the binding moiety in brain cytosol to be AFP with one binding site per molecule, 4-d brain cytosol should contain 1.8–1.9 μg of

Fig. 3 Glycerol gradient analysis of brain cytosol from mice of various ages incubated with ^{3}H-oestradiol. Cytosol from two or three female mice aged 1 (●), 4 (×), 10 (○) and 21 d(△) was incubated with 2 × 10⁻⁸ M ^{3}H-oestradiol. Samples of 0.4 ml containing 1.6, 2.6, 3.2, and 3.7 mg of protein, respectively, were centrifuged on glycerol gradients as in Fig. 1.

AFP per mg of protein. This is in close agreement with the observed AFP concentration (1.5 μg per mg of protein) at this age. The time course of disappearance of 4.6S oestradiol-binding activity in brain cytosol (Fig. 3) parallels the decrease in AFP levels. At 1 and 5 d substantially all the ^{3}H-radioactivity was found in the 4.6S peak (at 5×10[-9] ^{3}H-oestradiol). At 10 d there was an appreciable decrease in the proportion of bound ^{3}H-oestradiol, with a concomitant increase in free steroid at the top of the gradient, and by 21 d no binding was detectable.
Fig. 4 Glycerol gradient analysis of brain cytosol from 5-d-old male mice incubated with ^{3}H-oestradiol after treatment with anti-mouse AFP or an unrelated control adsorbent. Cytosol was treated with Sepharose-coupled anti-mouse AFP antibodies (○) or with control adsorbent (●) for 3 h at 0 °C and incubated with 5×10[-9] M ^{3}H-oestradiol. Samples of 0.5 ml containing 2.5 and 2.2 mg of protein, respectively, were centrifuged on glycerol gradients as in Fig. 1. The scale on the left refers to the expanded plot of the bottom part of the gradients showing the peaks of 8S oestradiol receptor.

Treatment of 5-d brain cytosol with anti-mouse AFP antibodies insolubilised on to Sepharose removed almost completely the 4.6S oestradiol-binding activity, while this binding was not affected in a sample treated with an unrelated control Sepharose adsorbent (Fig. 4). The binding data were in agreement with measurements of AFP in these samples: these were 0.12 and 1.4 μg of AFP per mg of protein, respectively. In contrast, there was no change in the oestradiol-binding capacity of the 8S oestradiol receptor[13] after exposure of cytosol to anti-mouse AFP. A second experiment involving 1-d brain cytosol gave essentially the same results.

Thus FEBP in neonatal mouse brain cytosol has properties similar to those of purified mouse AFP with respect to affinity for 17β-oestradiol, specificity of the binding reaction and sedimentation rate in glycerol gradients. In addition, AFP can be detected in cytosol preparations by immuno-diffusion or radioimmunoassay, and AFP and 4.6S oestradiol-binding activity show a similar time course of disappearance in the developing brain and coincident removal from brain cytosol by anti-mouse AFP antibodies. By all these criteria AFP and FEBP are substantially identical.

The biological role of AFP is unclear, but its high capacity for oestradiol (and oestrone) has led to the idea that it may be involved in the protection of foetal tissues against circulating maternal oestrogens[1,4]. This may be particularly

important in the brain because the FEBP-AFP concentra-tion in brain cytosol seems to be higher than can be accounted for by contamination from the blood[1,4]. The oestrogen-binding properties of AFP, however, may be confined to rodents and this may not be the only function of this protein. This is suggested by the lack of significant oestrogen binding, demonstrable by equilibrium dialysis or gradient centrifugation, by human AFP-containing serum or amniotic fluid[15,16] or by purified human and bovine AFPs (our unpublished results). Also AFP shows sequence homo-logy with serum albumin[17], and oestrogen binding may be only a specialised expression of general albumin-like binding properties of the AFP molecule.

Inhibition of platelet aggregation by a myeloma protein with anti-phosphocholine specificity

PHOSPHOCHOLINE-containing phospholipids, particularly phosphatidylcholine (lecithin), lysophosphatidylcholine and sphingomyelin, have integral roles in the structure and function of mammalian cell membranes[1]. Enzymatic diges-tion of platelet choline phosphatides, particularly of phos-phatidylcholine which is the most abundant of the platelet phospholipids[2,3], has been shown to induce platelet release reactions[4]. We have demonstrated that C-reactive protein (CRP), an acute phase reactant with binding specificities for phosphocholine, choline phosphatides and polycations generally[5,6], can inhibit multiple platelet reactivities[7,10]. These considerations have raised the possibility that mole-cules generally with binding specificities for choline phos-phatides can influence platelet responsiveness. We report here an investigation of the ability of the T-15 anti-phospho-choline mouse IgA myeloma protein to inhibit the aggre-gating response of human platelets.

Diluents and human platelets were prepared and platelet viability and aggregation were assayed as described before[8]. The IgA-producing plasma-cell tumours TEPC-15 and MOPC-315 were provided by Dr Donald A. Rowley, Univer-sity of Chicago, and were maintained in BALB/cJ mice (Jackson Laboratories). The anti-phosphocholine myeloma protein T-15 was isolated by affinity chromatography from pools of ascites fluid obtained from tumour-bearing mice essentially by the method of Chesebro and Metzger[11], except
Fig. 1 The effects of increasing amounts of T-15 on platelet aggregation induced by thrombin (0.2 units ml^{-1}) (a) and AHGG (50 µg ml^{-1}) (b); the concentrations of T-15 added to the reaction mixtures are expressed in µg ml^{-1}.

that C-polysaccharide-Agarose beads[12] were used in place of phosphocholine-Agarose. The protein was purified further by filtration on BioGel A-0.5 m, and the material reactive with rabbit anti-mouse IgA antiserum corresponding to the 11S dimer was used. Similarly, the anti-dinitrophenol myeloma protein M-315 was isolated from pools of serum and ascites fluid obtained from mice bearing MOPC-315 by affinity chromatography on trinitrophenylaminoethyl Agarose beads (BioGel, A-15 m); it was eluted with 0.1 M dinitrophenol, and the dinitrophenol was removed on Dowex 1 (ref. 13).

The T-15 mouse IgA myeloma protein reactive with phosphocholine was found to inhibit the ability of washed human platelets to aggregate in response to thrombin and aggregated human γ globulin. This inhibition was characterised by a reduced rate (slope) and extent (amplitude) of aggregation, and a decreased size of the platelet aggregates formed (magnitude of the vertical oscillations); concentrations as low as 25–80 µg ml^{-1} were sufficient to bring about these effects (Fig. 1).

By contrast, the M-315 mouse IgA myeloma protein did not inhibit aggregation at concentrations as high as 425 µg ml^{-1}, indicating that the inhibition by T-15 involved its antigen-combining site. In support of this interpretation, inhibition by T-15 was reduced substantially when phosphocholine was included in the reaction mixtures (Table 1).

Table 1 Effect of phosphocholine on T-15-inhibited aggregation of platelets stimulated by thrombin and AHGG

Inhibitor	% Inhibition ± s.d.*	
	Thrombin	AHGG
T-15	56 ± 10.0	54 ± 7.1
T-15 + PC	15 ± 7.1	26 ± 1.4
PC	1 ± 0.5	2 ± 1.4

Platelets (3 × 10⁹) were equilibrated with T-15 for 1 min at 37 °C and challenged with thrombin (0.2 units ml^{-1}) or AHGG (50 µg ml^{-1}); aggregation was recorded for 5 min. The concentration of T-15 chosen was sufficient to inhibit the rate of aggregation by approximately 50% and represents 60 (thrombin) and 80 (AHGG) µg ml^{-1}; phosphocholine (PC) was at a final concentration of 10⁻³ M.
*The data are presented as the percentage inhibition in the rate of platelet aggregation ± 1 standard deviation (s.d.) as compared to the aggregation response obtained in the absence of inhibitors.

The possibility that T-15 acts by reducing platelet viability was discounted because concentrations far in excess of those used in this study (>950 µg ml^{-1}) were not cytotoxic as determined by incorporation of ^{14}C-5-hydroxytryptamine (^{14}C-5-HT) and release of lactic dehydrogenase.

Thus, the T-15 myeloma protein with anti-phosphocholine specificity inhibits the reactivity of human platelets with characteristics similar in all respects investigated to those previously observed when CRP was added to these mixtures. It had not been clear whether CRP reacts with phosphocholine lipids, polycations or other of its binding specificities to cause its inhibitory effect. Our data suggest that a phosphocholine moiety on the platelet surface is involved in this inhibition, and that phosphocholine-binding molecules generally can modulate platelet reactivities; CRP would seem to be biologically the most important of the latter. The anti-phosphocholine myeloma protein may well aid in the delineation of the surface receptors and pathways involved in the CRP-mediated control not only of platelet reactivities, but also of responses of other cells reactive with CRP, such as subpopulations of T cells[14-16]. The nature of these receptors, and the significance of the association of molecules with which they interact with inflammation and tissue destruction, seem to be critical to a more complete understanding of body defence mechanisms.

Antiviral antibodies inhibit the lysis of tumour cells by anti-H-2 sera

RECENT experiments have indicated that the cytolysis of virus-infected, chemically modified, or neoplastic cells by murine T lymphocytes is restricted to target cells carrying one or more of the H-2 antigens possessed by the cells against which the cytotoxic T cells were generated[1-10]. Two general hypotheses have been proposed to explain the participation of H-2 antigens in T-cell-mediated cytolysis. According to one hypothesis, T lymphocytes possess two different types of receptors, one which recognises the abnormal antigens of the target cell, and a second which interacts with the H-2 antigens of that cell. In the alternative hypothesis, the T cell has only one specific receptor that is directed against a complex antigenic determinant made of of H-2 antigens and viral antigens, for example, tumour antigens induced by viral infection. Neither of these hypotheses has yet been satisfactorily proven. In support of the one-receptor hypothesis, we have found that anti-H-2 and antiviral sera show copatching and cocapping of H-2 and viral antigens on the surface of EL4 leukaemia cells[a], suggesting that viral and H-2 antigenic determinants can be in close physical association on the cell surface. Here we provide new evidence for the existence of a close association between H-2 antigens and viral antigens on murine leukaemia cells.

We have used the method of antibody-induced resistance to complement-dependent lysis ("lysostrip" technique[11]) to show that the binding of antiviral antibody to the cell surface resulted in resistance to cell lysis induced by subsequent treatment with anti-H-2 serum and complement. Bernoco *et al*.[11] and Hauptfeld *et al*.[12] have shown that specific resistance to lysis by an alloantiserum can be effected by first coating cells with the alloantiserum and then incubating the cells with an anti-Ig serum directed against the first antibody.

Treatment of EL4 cells (H-2ᵇ) with a rabbit antiserum to Rauscher leukaemia virus (RLV), or with a goat antiserum against the purified glycoprotein gp70 of murine leukaemia virus (Scripps), and then with an appropriate anti-Ig reagent reduced the subsequent complement-mediated lysis of the cell by anti-H-2ᵇ antiserum (Table 1). In contrast, both of the antiviral antisera had only slight and inconsistent effects in similar experiments using normal lymphocytes from the parental mouse strain C57BL/6 (Table 1). The corresponding control sera (normal rabbit serum taken before immunisation with RLV or pooled normal goat serum) had no effect either on EL4 cells or spleen cells. Before use, all of the heterologous sera were absorbed at least twice with equal volumes of normal spleen cells.

The efficiency and specificity of the "lysostrip" technique was demonstrated on both normal spleen cells and tumour cells. Pretreatment with antisera to the H-2Dᵇ antigens caused no reduction or very little reduction in the

susceptibility to lysis by an anti-H-2Kᵇ antisera (Table 1). Similarly, precoating the cells with antiserum to the H-2Kᵇ antigens caused no reduction in susceptibility to lysis by anti-H-2Dᵇ serum (Table 1) Precoating the cells with an anti-H-2Kᵇ antiserum, however, did lead to an increased lysis in the cytotoxicity assay performed with an anti-H-2Dᵇ antiserum. This increase was probably due to anti-H-2Kᵇ antibodies that had bound to the cells and were present during the cytotoxic assay. It was not observed if the precoated cells were treated with goat antibody to mouse IgG, which also suggests that it was due to anti-H-2Kᵇ antibodies that were bound in the first step of the experiment.

These results confirm that resistance to lysis can be induced only by redistribution of the H-2 antigen specifically tested in the cytotoxicity assay, as reported by Hauptfeld *et al.*[11]. The observation that the pretreatment of EL4 cells with antiviral sera induced a partial resistance to cytotoxicity mediated by alloantisera against both the K and the D end of the major H-2 complex is therefore not likely to be a peculiarity of the method that we used.

The identity of the relevant viral antigens carried by the EL4 cells is unknown Sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis of immune precipitates
Fig. 1 SDS–polyacrylamide gel electrophoresis of an immuno-precipitate of an extract of ¹²⁵I-surface-labelled EL4 cells. EL4 cells were iodinated with ¹²⁵I by the lactoperoxidase technique[21] and extracted with 0.5% NP40 (ref. 19). Immuno-precipitates were obtained using BALB/c absorbed RLV and unabsorbed GARIgG. SDS gel electrophoresis was performed in 8 5% polyacrylamide gels after solubilisation and reduction of the precipitates by boiling for 5 min in sample buffer containing 4% SDS and 5% mercaptoethanol[19]. MOPC 21 myeloma immunoglobulin labelled with ¹³¹I was used as marker. γ, Heavy chain (molecular weight, 50,000);κ, light chain (molecular weight, 23,000); BPB, bromophenol blue marker.

made from ¹²⁵I-labelled EL4 cells using RLV, however, showed a major component corresponding in mobility to the viral glycoprotein gp70 (Fig. 1). Similar results were obtained with goat antisera against the gp70 glycoproteins of Rauscher leukaemia virus[13] or murine leukaemia virus (Scripps). All three antiviral antisera also stained the EL4 cells brightly by immunofluorescence. Viral antigens were not detected on C57BL/6 spleen cells with these antisera by either immunofluorescence or immune precipitation.

Of the artefacts that might arise in these experiments, the most obvious would be ascribable to antiviral antibodies in the anti-H-2 antisera[13-15] or anti-H-2 antibodies in the antiviral antisera. Several kinds of control experiments were performed to explore these possibilities. Most

RLV, rabbit antiserum against Rauscher leukaemia virus; GARIgG, goat antiserum against- rabbit IgG; NRS, normal rabbit serum; GAgp70, goat antiserum against gp70; RAGIgG, rabbit antiserum against goat IgG; NGS, normal goat serum; GAMIgG, goat antiserum against mouse IgG. The procedure was performed in three steps. Step I. 5×10^5 ^{51}Cr-labelled cells were coated with 0.02 ml antiviral or anti-H-2 antibody in 0.2 ml Minimal Essential Medium with 5% heat-inactivated foetal bovine serum (MEM/FBS) for 30 min on ice. Step II. After washing twice, cells were incubated for 45 min at 37 °C in 0.2 ml MEM/FBS with 0.02 ml of a second antiserum directed against the first antibody. Cells were washed once and this step was repeated. After completion of this second cycle cells were washed once and resuspended in 0.22 ml MEM/FBS. Step III. Cytotoxicity assay was performed using 2×0.05 ml of this cell suspension as described earlier[19] using antisera directed against the H-2K^b or H-2D^b antigens as indicated (*). Total c.p.m. were determined in 2×0.05 ml of the same cell suspension. Results are given in percentage specific lysis calculated according to the following formula:

$$\frac{\text{Experimental c.p.m.} - \text{background c.p.m.}}{\text{Total releasable c.p.m.} - \text{background c.p.m.}} \times 100$$

Background lysis was determined separately and varied between 14 and 30%. Each antiserum used was also tested individually to exclude nonspecific lysis due to incomplete absorption. EL4 cells (Salk Institute) were grown in ascitic form in C57BL/6 mice (Jackson Laboratory). Splenic lymphocytes were prepared by the Ficoll-Hypaque technique[20]. Cells were labelled with 100 μCi of ^{51}Cr per 10^7 cells. Antisera used in step I were anti-H-2K^b (H-2.33) and anti-H-2D^b (H-2.2) prepared as described earlier[19] and were used undiluted. RLV was produced by repeated injections of SDS-solubilised Rauscher leukaemia virus (Litton Bionetics) adding complete Freund's and incomplete Freund's adjuvant, respectively, in the first two injections. RLV was absorbed twice with equal volumes of packed C57BL/6 spleen cells or with BALB/c spleen cells (H-2^d) when used on C57BL/6 spleen lymphocytes. NRS was obtained from the rabbit producing the RLV before the first immunisation and was absorbed by the same procedure. GAgp70 raised against gp70 isolated from murine leukaemia virus (Scripps), and pooled NGS were absorbed in the same way as the rabbit sera. Antisera used in step II were GAMIgG (Miles-Yeda, Rehovot) was absorbed with BALB/c thymus cells. GARIgG prepared by repeated injections of rabbit IgG was absorbed with BALB/c spleen and thymus cells, and RAGIgG (Cappel Laboratories) was absorbed with BALB/c spleen cells. In the cytotoxic assay the antiserum against H-2K^b was used at a dilution of 1:18 (except K^b†, dilution: 1:12) and the antiserum against H-2D^b was used at 1:8. Guinea pig complement (Grand Island Biologic. Co., Grand Island) was absorbed with mouse spleen cells and diluted 1:4. Each vertical column represents a single experiment. Results indicating that pretreatment has reduced the susceptibility to complement-mediated lysis by anti-H-2 sera are underlined. When anti-H-2D^b serum was used in the cytotoxicity assay, there was increased specific lysis of cells that had been pretreated with RLV or anti-H-2D^b serum alone. For this reason, the lysostrip effect is probably best estimated by comparing the specific lysis of cells pretreated with the first antibody and then anti-Ig antibodies, with the specific lysis of cells pretreated only with the first antibody or only with anti-Ig antibodies.

mouse alloantisera contain antibodies directed against murine leukaemia antigens[14,15] and particularly against the envelope protein gp70 (refs 13-15). The cytotoxic activity of certain alloantisera against tumour cells may therefore consist of two components, one due to antibodies against alloantigens and the other to antibodies against viral antigens. Accordingly, the anti-H-2^b sera used in this study were absorbed three times with equal volumes of packed thymocytes of young BALB/c mice (H-2^d) or with NZB-thymoma cells that were actively producing murine leukaemia virus (Scripps) in large amounts (SCRF 60A, H-2^d). After absorption, the titres of the anti-H-2K^b and anti-H-2D^b sera were compared using EL4 cells as targets. There was no difference in the cytotoxic titres after absorption with either normal thymocytes or virus-producing tumour cells.

This result indicated that our cytotoxicity assay did not detect anti-viral antibodies in the anti-H-2 antisera. It is therefore unlikely that the decreased cytotoxic effect of the anti-H-2 antisera after redistribution of viral antigens merely reflects the absence of cytolysis that might have been due to the presence of antiviral antibodies in the anti-H-2 antisera. It should be noted that small amounts of anti-viral antibodies were present in the anti-H-2D^b antiserum, however, inasmuch as a gp70 component was

observed in the SDS-gel electrophoretic analysis of immune precipitates made from ^{125}I-labelled EL4 cells or C57BL/6 spleen cells[13]. On the other hand, immune precipitates using the anti-H-2K^b antiserum on extracts of EL4 or C57BL/6 cells did not contain detectable amounts of viral antigens[13].

The specificity of one of the anti-viral antisera used (RLV) was demonstrated by comparing the "lysostrip" effect of RLV on EL4 cells after absorption with either C57BL/6 spleen cells or with the cell line SCRF 60A (H-2^d) that produces murine leukaemia virus (Scripps). Pretreatment with 4 or 0.8 μl of the RLV that had been absorbed with SCRF 60A (H-2^d) cells did not reduce subsequent cytolysis by H-2K^b antiserum in contrast to pretreatment with similar amounts of the RLV that had been absorbed with C57BL/6 spleen cells (Table 2). The difference between the absorption with virus-producing cells and with normal spleen cells suggests that the effect of RLV in the lysostrip assay is due to antibodies directed against viral antigens rather than to antibodies against H-2 antigens. Similar experiments showed that absorption of the H-2K^b antiserum with C57BL/6 spleen cells completely abolished its ability to induce resistance against anti-H-2K^b mediated cytotoxicity.

These observations confirm and extend our previous

observations on the cocapping of H–2 and viral antigens[8] using the same cell type (EL4) and similar antisera. Both sets of data are explicable in terms of a close physical association or inter-action of viral and H–2 determinants on the cell surface. Because the exact mechanism of the lysostrip phenomenon is not understood, however, the present results are not conclusive evidence for the close molecular association of viral and H–2 determinants in all conditions. Obviously, more direct approaches are required to demonstrate an association at the molecular level.

Although the evidence that viral and H–2 determinants may be associated on the cell surface is only indirect, it is difficult to account for by any other means. It is therefore pertinent to consider the possible mechanism of this molecular association. One possibility is that both viral and H–2 determinants are on one molecule[16]. There are no biochemical data to favour this model, but it cannot be completely excluded at present. We have observed, however, that target cells coated with inactivated Sendai virus are killed by specific cytotoxic T cells within the first 30 min after the cells are coated with the virus[2]. These experiments suggest that any synthetic modification of the H–2 antigens that might occur must be induced very rapidly, a finding that further weakens the hypothesis.

A second possibility, which we favour[9], is that viral and H–2 antigens are in close physical association on the cell membrane. The molecular interaction between the H–2 and viral antigens could be related to a specialised function of either of the molecules. For example, H–2 antigens

Table 2 Effect of absorption of RLV with a cell line producing murine leukaemia virus (Scripps)

0.4	38	36

RLV was absorbed twice with equal volumes of packed SCRF 60A cells (grown in RPMI 1640 medium with 5% FBS) or with C57BL/6 spleen cells (H–2[b]). The lysostrip technique was performed on EL4 cells as described in the legend of Table 1 using the indicated volumes of the absorbed RLV sera in the first step, and GARIgG in the second step. Sensitivity to cytotoxicity was assayed using anti-H–2K[b] (1:18). Specific lysis was calculated as described in Table 1. The specific lysis of control cells pretreated only with RLV and not with GARIgG was 43% for the RLV absorbed with C57BL/6 cells, and 40% for the RLV absorbed with SCRF 60A cells.

could have a broad binding specificity for a wide range of viral antigens or could serve as receptors for viruses. Alternatively, H–2 antigens may have a tendency to bind weakly to many surface proteins. This might account for the finding that T-cell-mediated cytotoxicity against minor histo-compatibility antigens also seems to involve the H–2 antigens[17,18]. Although the direct demonstration of hybrid antigens does not in itself exclude the hypothesis that the T cell has two separate recognition sites, one for H–2 and the other for viral antigens, a variety of experiments favours the idea that the T cell has a single kind of receptor for recognition of hybrid antigens.

murine leukaemia virus protein gp70, and for NZB-thymoma cells producing murine leukaemia virus (Scripps).

GABA-mediated control of rat neostriatal tyrosine hydroxylase revealed by intranigral muscimol

BLOCKADE of central dopamine (DA) receptors by neuroleptic drugs is associated with an increase in the firing rate of nigro-neostriatal DA neurones[1] and an enhanced turnover rate of DA in neostriatum (caudate–putamen)[2,3].
Fig. 1 Tyrosine hydroxylase (TH) activity from the right (open bars) and left (darkened bars) caudate–putamen of rats treated with saline (Sal) or muscimol directly into the left substantia nigra by way of chronically implanted stainless-steel cannulae. Muscimol was dissolved in saline and administered in a volume of 0.3 μl, over a 3-min period. Ten minutes after intranigral injection, haloperidol (1.0 mg kg[−1] dissolved in 0.05% acetic acid, intraperitoneally) or its vehicle alone (first pair of bars) was administered intraperitoneally. Animals were decapitated 40 min after intranigral injection and the tissue to be assayed was rapidly dissected out and frozen on dry ice. Assay for TH was done according to the method of Zivkovic et al.[3]. Values shown were obtained using 0.3 mM DMPH$_4$ cofactor and 0.1 mM tyrosine. Each value represents the mean of eight rats (bar indicates s.e.). *$P < 0.05$ when compared with the contralateral (control) side.

At the molecular level, the neuroleptic-induced increase of caudate–putamen (CP) DA metabolism is maintained by a decrease in the K_m of tyrosine hydroxylase (TH), for pteridine cofactors[4-6]. This increase in affinity of TH for cofactor occurs within 20 min of a single injection of a neuroloptic such as haloperidol or pimozide and lasts for at least 2 h. The action of haloperidol and other neuroleptics on CP–TH activity is abolished by either mechanical (lesion) or functional (γ-butyrolactone) interruption of nigro-neostriatal DA projections[7-9]. It is likely, therefore, that the neuronal "feedback loop" hypothesis, proposed originally by Carlsson and Lindqvist[3] to explain the regulation of nigro-neostriatial DA biosynthesis, is also relevant to the acute activation of CP–TH after systemic administration of neuroleptics. According to this theory, a neural pathway from neostriatum to substantia nigra (SN) is responsible for mediating an increase in presynaptic DA function in an effort to compensate for reduced neostriatal postsynaptic DA receptor activity.

Histochemical studies have demonstrated the presence of a GABA-containing pathway originating in the caudate nucleus with terminal projections in close proximity to soma and dendrites of nigral DA neurones[10-14]. Electro-physiological evidence indicates that the GABAergic neurones in the striatonigral pathway exert a picrotoxin-sensitive, inhibitory influence on nigral cells[15]. It is possible that a reduced release of GABA from these descending inhibitory neurones may occur as a result of neuroleptic blockade of CP–DA receptors. Activation of CP–TH could then occur as a consequence of the decreased GABAergic inhibitory control of nigral DA neurones.

The experimental verification of this hypothesis was made

possible by the use of muscimol. This isoxazol derivative, with a restricted conformation similar to that of GABA, displays bicuculline-sensitive and strychnine-insensitive inhibitory activity both *in vivo* and *in vitro*[16,17], but unlike GABA is not rapidly metabolised and thus exhibits long lasting GABA-mimetic effects *in vivo*[18]. Moreover, on the basis of experiments with a DA-sensitive adenylate cyclase, we have established that this compound is devoid of any DA-agonist or antagonist potency in homogenates of neostriatum or substantia nigra.

Muscimol was injected directly into the SN by way of chronically implanted cannulae (for detail see Figs 1 and 2). Ten minutes later haloperidol ($1.0 \, mg \, kg^{-1}$) was administered intraperitoneally and the animals were killed 30 min later for TH assay. In this experiment, TH was assayed using a concentration of cofactor ($DMPH_4$) below that required to saturate the enzyme fully.

Figure 1 shows that the haloperidol-induced increase of CP–TH activity was blocked in the caudate ipsilateral to the intranigral application of muscimol. A 50% reduction of the action of haloperidol was obtained by injection of 25 ng of muscimol into the SN; 50 ng of muscimol reliably and completely prevented the action of haloperidol on CP–TH. Muscimol (50–400 ng) alone did not alter normal CP–TH activity when measured at 20 and 40 min after intranigral injection.

The differences in the values for TH activity presented in Fig. 1 were found to reflect differences in the apparent K_m values of TH for the pteridine cofactor. Double-reciprocal plots of TH activity obtained in the presence of different cofactor concentrations and K_m values for normal, haloperidol-"activated", and muscimol-"protected" CP–TH
Fig. 2 Double-reciprocal plots of the initial velocity of CP–TH against various concentrations of $DMPH_4$ in the presence of 0.1 mM tyrosine. Experimental design was as described in Fig. 1. Muscimol (○, 50 ng; ●, 25 ng) or saline (×) was injected into the substantia nigra (SN). Ten minutes after intranigral injection, haloperidol (1 mg kg^{-1}) was administered intraperitoneally. The animals were killed 40 min after the intranigral injection. Control rats (▲) received saline intranigrally and vehicle intra-peritoneally. Insert: photomicrograph of coronal section of rat brain (left hemisphere) showing position of (22 g) guide-cannula tip (blackened area above the dorsal border of the SN). Injection cannula (27 g) extended 0.8 mm below guide cannula into the pars compacta region of the SN.

are shown in Fig 2. It is clear that intranigral muscimol treatment (50 ng or more) prevented the marked decrease (two- to three-fold) in apparent K_m caused by haloperidol treatment. Similar results were obtained with pimozide (1.0 mg kg^{-1}) treatment.

To determine whether the effect of intranigral muscimol was specific for the DA neurones projecting to the neostriatum, we assayed the TH activity of the nucleus accumbens of eight rats which received 25 ng of intranigral muscimol and 1.0 mg kg^{-1} haloperidol intraperitoneally. In these animals, the percentage differences between the two neostriata averaged 55% (range 40–70%), with the muscimol-treated side exhibiting lower TH activity. In contrast, the maximum bilateral difference obtained for the nucleus accumbens was less than 10%, both sides showing the usual TH activation after haloperidol. This attests to the anatomical specificity of the GABA influence on nigral DA neurones, and moreover demonstrates the degree of functional localisation for the material injected.

Data obtained from a series of rats which received intranigral bicuculline suggest that the effects we observed with muscimol are attributable to a specific GABA-mimetic action. Bicuculline methiodide (2.0 nmol per 0.4 μl over 2 min) was injected into the SN 20 min after 0.4 nmol of muscimol (50 ng). Haloperidol (1.0 mg kg^{-1} intraperitoneally) was injected 10 min before bicuculline. Control animals received muscimol and haloperidol, but with saline or strychnine (4.0 nmol per 0.4 μl over 2 min) replaced bicuculline. In all control animals, the apparent K_m of CP–TH for cofactor was 0.8 mM on the muscimol-treated side and 0.3 mM on the contralateral side. In contrast, CP–TH of all bicuculline-treated animals showed no significant bilateral differences: in every case the TH of both neostriata exhibited K_m values (0.25–0.33 mM) characteristic of haloperidol activation. Bicuculline alone had no effect on TH activity, but reversed the muscimol blockade of haloperidol-induced TH activation, and caused the dose–response relationship for muscimol to shift to the right approximately twofold. Since bicuculline (a putative GABA receptor antagonist[19]), but not strychnine (a glycine receptor antagonist[19]), reversed the action of muscimol and reinstated the effect of haloperidol on CP–TH activity, it is likely that GABA receptors mediate the action of muscimol in the SN.

Our data demonstrate that it is possible to interfere with haloperidol-induced activation of CP–TH by pharmacologically maintaining the functional effect of GABA on nigral neurones. It is unlikely that the muscimol–haloperidol interaction occurred directly in the nigra, since in other experiments we found that application of haloperidol (10^{-6}–10^{-9} M) directly into the nigra did not alter CP–TH activity. Thus the release of DA by nigral dendrites[20,21] and a postulated self-inhibitory action of DA in SN[1,22] may not be relevant to the mechanism of neuroleptic activation of CP–TH. Instead, it seems that haloperidol acts to change activity in nigral neurones indirectly, as a result of its action in the neostriatum. We suggest therefore that application of muscimol directly into the nigra, by mimicking GABA, acted to preclude the influence of a striatonigral feedback pathway. This implies that a decrease in GABA release in nigra is required for the neuroleptic-induced activation of CP–TH, a contention supported by the ability of bicuculline to reinstate TH activation after muscimol blockade.

Temperature-dependent inhibition of evoked acetylcholine release in tick paralysis

IN AUSTRALIA, the tick *Ixodes holocyclus* can produce a potentially fatal, flaccid paralysis in various hosts, including man, apparently due to the secretion of a neurotoxin[1,2]. In other parts of the world other species of ticks can produce a similar syndrome[3], but it is not yet clear whether the pathogenesis of the paralysis is the same in all cases. We have found that the paralysis produced by *I. holocyclus* is due to a temperature-dependent inhibition of evoked release of acetylcholine at the neuromuscular junction.

Application of about 10 nymphal *I. holocyclus* produced paralysis in mice after 3.5–4.5 d, the exact period required depending on the rate of feeding of the ticks. Experiments were carried out on phrenic nerve–hemidiaphragm preparations removed from the most severely affected of these animals. These were mounted in a 2-ml bath and perfused continuously, at a rate of 1 ml per min, with modified Krebs' solution (120 mM NaCl, 3.5 mM KCl, 2.5 mM CaCl$_2$, 1.0 mM MgCl$_2$, 11 mM glucose, 25mM NaHCO$_3$) bubbled with 5% CO$_2$ in O$_2$. Temperature was monitored by means of a thermistor probe placed close to the recording site. The nerve was stimulated using a suction electrode and conventional intracellular techniques were used to record from the endplate region of muscle fibres. Microelectrodes were filled with 3 M KCl. Compound action potentials were recorded from the phrenic nerve using a second suction electrode. Direct stimulation of the muscle fibres was accomplished by silver wire electrodes placed on either side of the diaphragm.

At first the ability of muscles from paralysed animals to contract in response to nerve stimulation was assessed visually. At room temperature (approximately 23 °C) the muscle always contracted strongly. As the temperature was raised the response declined progressively, and at 37 °C no contraction was apparent. On subsequent reduction of the temperature the muscle response returned. The muscle contracted strongly in response to direct stimulation within this range of temperature. Similar results were obtained from all twenty preparations examined.

The effects of *d*-tubocurarine [*d*-TC] and increased magnesium chloride concentration (with compensation by reducing sodium chloride concentration) on paralysed preparations were also examined. At a concentration of 2.1 μM in the case of *d*-TC or 5 mM in the case of

magnesium chloride, the contractile response of the muscle ceased at a lower temperature than in normal solutions. At temperatures above 30 °C, no twitch occurred. In experiments on preparations from normal mice, the same concentrations of these drugs were insufficient to prevent muscle contraction.
Fig. 1 Graph showing effect of temperature on e.p.p amplitude at five endplates in three different affected animals. Dashed lines indicate endplates examined in 5 mM Mg[2+]; dotted line, an endplate examined in 2.1 µM d-TC. Each point represents the mean ($\pm$ s.e.) of approximately twenty responses.

Endplate potentials (e.p.p.s) were examined in these modified solutions. In the temperature range 15–30 °C, muscle fibres could always be found in which nerve stimulation produced e.p.p.s up to 10 mV in amplitude, but none were found above 30 °C. The mean amplitudes of e.p.p.s in muscle fibres from paralysed mice were markedly temperature dependent. As the temperature was increased, the mean amplitude fell and the number of stimuli failing to produce an e.p.p. increased. In each fibre the rate of decline of e.p.p. mean amplitude appeared to be approximately the same, but the temperature range over which the decline occurred differed. This is demonstrated in Fig. 1. The effect could be reversed by lowering the temperature. The amplitude of miniature endplate potentials (m.e.p.p.s) was not altered over this temperature range (Fig. 2).

In preparations from normal mice, the effect of temperature on transmitter release was examined in 8.4 µM d-TC or 12 mM Mg. There was no decline in e.p.p. amplitude, comparable with that seen in tick paralysed preparations, over the temperature range 25–37 °C (Fig. 3).

There was no decline in the amplitude of the compound action potentials recorded from phrenic nerves removed from paralysed preparations within this range of temperature. There was, as expected[4], a small increase in amplitude as temperature was increased.

It is unlikely that the paralysis is due to a selective failure of conduction in the nerve terminals. Krnjevic and Miledi[5] have shown that this type of failure can occur, but that it results in a sudden failure of e.p.p.s and is more likely to occur at low temperatures.

Another possibility is that the toxin produces, a temperature-dependent, graded reduction of action potential amplitude in the nerve terminals. This possibility has not been entirely eliminated. It seems unlikely, however, that the amplitude of the nerve terminal action potential could be reduced sufficiently to abolish transmitter release without a detectable effect on that of the nerve trunk.
Fig. 2 Endplate potentials and m.e.p.p.s from the same affected endplate at 26.5 °C (upper trace) and 28.5 °C (lower trace). Arrow indicates stimulus artefact.

Other workers[6,7] have suggested that the paralysis produced by the tick *Dermacentor andersoni* is associated with a reduction in amplitude of the compound action potential recorded from peripheral nerves *in vivo*. We found no evidence of this in our experiments and it may be that the modes of action of the toxins from the two species of tick differ. A central action for the toxin of *D. andersoni* has also been postulated[8,9]. Our observations, however, suggest that most aspects of the motor paralysis produced by *I. holocyclus* can be explained on the basis of action at the neuromuscular junction.
Fig. 3 Graph showing effect of temperature on e.p.p. amplitude in preparations from normal mice. Dashed line indicates an endplate examined in 12 mM Mg[2+]; dotted line an endplate examined in 8.4 µM d-TC. Each point represents the mean ($\pm$ s.e.) of approximately twenty responses.

The data presented here suggest that the toxin secreted by *I. holocyclus* has a direct, temperature-sensitive action on the excitation–secretion coupling mechanism, which results in an inhibition of transmitter release at the neuromuscular junction. This inhibition seems to be due to a reduction in quantal content, rather than quantal size, as the latter would be expected to result in m.e.p.p.s of reduced amplitude. Because spontaneous release continued when evoked release was blocked, it seems likely that the toxin does not interfere with the actual release mechanism, but rather with some intermediate step between depolarisation of the terminal membrane and release. An attractive

hypothesis is that the toxin blocks the influx of calcium ions which seems to be essential before evoked release can occur[10,11]. This remains to be investigated.

Mesolimbic dopaminergic neurones in the rotational model of nigrostriatal function

AT least some of the symptoms of Parkinson's disease are believed to result from the degeneration of nigrostriatal dopaminergic neurones which normally innervate the striatum. Parkinsonian patients have an abnormally low concentration of dopamine in this region of the basal ganglia[1,2], and parkinsonian symptoms can be alleviated by the dopamine precursor L-dopa[3]. A quantitative animal model which has proved useful in assessing the potential therapeutic value of drugs in the treatment of parkinsonism was described some years ago by Ungerstedt and Arbuthnott[4]. Rats, in which the nigrostriatal pathway has been destroyed unilaterally by 6-hydroxydopamine (6-OHDA), were shown to rotate towards the lesioned side when injected with drugs, such as amphetamine, which release dopamine from neurones in the brain, and towards the unlesioned side when injected with L-dopa and dopamine agonists[5,6]. This contralateral rotation has been attributed to supersensitivity of the denervated striatal dopamine receptors[5,6].

We have investigated now whether another system of dopaminergic neurones, the mesolimbic system is involved in the drug-induced rotational behaviour. This system, comprised of dopaminergic neurones which originate in the A10 group of cell bodies and which innervate the nucleus accumbens and olfactory tubercle[7], has recently been shown to be important in the locomotor behaviour produced by various drugs[8-15]. In a recent study of the possible role of mesolimbic dopamine neurones in rotational behaviour it was shown that amphetamine and the dopamine agonist apomorphine caused no rotation in rats with unilateral 6-OHDA-induced destruction of mesolimbic dopamine neurones[16]. However, it remained possible that bilateral destruction of the mesolimbic dopamine system could affect the drug-induced rotation of rats with unilateral lesions of the nigrostriatal pathway. We have now found this to be the case.

Adult male Sprague–Dawley albino rats received an intrastriatal injection of 6-OHDA into the right caudate nucleus and during the same operation bilateral injections of 6-OHDA or vehicle into the nucleus accumbens. 6-OHDA injections were made stereotaxically while the rats were anaesthetised with Equithesin (3 ml kg⁻¹). Stereotaxic coordinates for the nucleus accumbens were $+3.4$, 1.7, 7.2 according to the atlas of Pellegrino and Cushman[17], and for the caudate nucleus were $+2.0$, 3.0, 5.5. Injections were made through a 30-gauge stainless steel cannula at the rate of 1 μl min⁻¹. Eight micrograms (calculated as base) of 6-hydroxydopamine hydrobromide (Sigma), dissolved in 0.9% saline containing ascorbic acid (1 mg ml⁻¹) was injected in a volume of 2 μl. Vehicle injections were identical except for the omission of 6-OHDA from the solution. At various times following these lesions the rotation induced by intraperitoneal injections of (+)-amphetamine sulphate or the dopamine agonist apomorphine (hydrochloride) was measured. The rats were placed in hemispherical white plastic bowls and the number of turns per min recorded every 10 min by direct observation. Fifty-five to sixty days after the operation the rats were killed by decapitation and their brains removed for the measurement of regional catecholamine content. The brains were chilled on an ice-cold glass plate and the olfactory tubercles, nuclei accumbens, right and left striata, and neocortex were dissected as described previously[18,19]. Tissues were homogenised in 0.1 N perchloric acid containing 0.1 mg ml⁻¹ EDTA and assayed for noradrenaline and dopamine by a radioenzymatic method[20] modified from that of Cuello *et al.*[21] The significance of statistical differences was calculated using Student's *t* test.

Fig. 1 shows the dopamine concentration in the nucleus accumbens and striata of the two groups of animals. In both groups the dopamine content of the right striatum was reduced to 35% of that of the left ($P<0.01$). In addition, the 6-OHDA lesion of the nucleus accumbens reduced the dopamine content of the nucleus accumbens to 25% of control ($P<0.01$) and that of the olfactory tubercle to 41% (6.7 ± 0.6 against 2.7 ± 0.4 μg g⁻¹, $P<0.01$). Neocortical noradrenaline content also was reduced to 49% (0.35 ± 0.01
Fig. 1 Diagrammatic representation of the dopamine concentration (μg g⁻¹) in the nucleus accumbens and left and right striata of the two groups of rats (7 rats per group) used in the circling experiments. Shaded areas indicate 6-OHDA (8 μg in 2 μl) was injected into the region.

against 0.17 ± 0.01 μg g⁻¹, $P<0.01$) of control by the nucleus accumbens lesion.

Figure 2 shows the responses of the two groups of animals to intraperitoneal injections of amphetamine (5 mg kg⁻¹) and apomorphine (0.5 mg kg⁻¹). The effect of the 6-OHDA lesion of the nucleus accumbens was to block the ipsilateral rotation produced by amphetamine, and to enhance the contralateral rotation produced by apomorphine. Although the 6-OHDA lesion of the nucleus accumbens destroyed both mesolimbic dopamine neurons and noradrenergic neurones innervating the neocortex we believe the behavioural effects

of the lesion result from the destruction of mesolimbic dopamine neurones as we have recently obtained similar results when rats were treated with desipramine before the 6-OHDA injection. This pretreatment protects noradrenergic neurones from destruction by 6-OHDA[13,22]. It therefore seems that activity in the mesolimbic dopaminergic system is as important as an imbalance of striatal dopaminergic activity for the expression of drug-induced rotational behaviour. When amphetamine-induced release of dopamine from mesolimbic neurones is prevented by their destruction amphetamine-induced rotation is blocked. The rotation produced by the directly acting dopamine agonist apomorphine, however, is enhanced, presumably because the denervated mesolimbic dopamine receptors become supersensitive.

These findings have implications for the use of rotational models in assessing the effects of drugs as agonists or antagonists at dopamine receptors. First it is clear that the drug-induced rotation of rats with unilateral 6-OHDA-induced destruction of nigrostriatal neurones is not a pure model of striatal dopaminergic mechanisms. Rather it seems that rotational behaviour depends on an imbalance of striatal dopaminergic activity plus activity in the mesolimbic dopamine system. The predominant effect of activity in the mesolimbic system seems to be on the rate of circling rather than its direction. In contrast to the nigrostriatal system there appears to be no directional influence of mesolimbic dopaminergic activity. Rats with unilateral 6-OHDA-induced destruction of mesolimbic dopamine neurones do not rotate in response to amphetamine or apomorphine[16]. Neither do unilateral injections of dopamine agonists into the nucleus accumbens cause any rotation[15].

As a tool for screening potential dopamine agonists and antagonists the rotation model remains useful. It would, however, be wrong to assume that the effects of dopamine agonists and antagonists in this preparation were due solely to their effects on striatal dopaminergic mechanisms. For example, drug-induced rotation would be blocked by drugs which blocked only mesolimbic or only striatal dopamine receptors. This point may be of more than theoretical interest as there is some evidence for differences between mesolimbic and striatal dopamine receptors[24]. The rotation produced by dopamine agonists can clearly be affected by the actions of the drug on mesolimbic dopamine receptors,

but our results do not predict whether a drug must act as an agonist at both mesolimbic and nigrostriatal dopamine receptors to produce rotation. It is conceivable, for example, that activation of nigrostriatal dopamine receptors by the drug and release of endogenous dopamine in the mesolimbic system would be sufficient to cause rotation. However, after injections of dopamine or dopaminergic agonists into the striatum the major effect seems to be postural asymmetry rather than a quantitative rotational response[23]. Activation of mesolimbic dopamine receptors by dopamine agonists may therefore be a necessary condition for these drugs to produce rotation.

Our results show that a drug-induced behavioural expression of nigrostriatal output, rotation, is markedly modified by the concomitant activity at mesolimbic dopamine receptors. Probably, therefore, activity at mesolimbic dopamine receptors can modify the effects of nigrostriatal activity in the undrugged animal, and the mesolimbic and nigrostriatal systems may interact physiologically in the control of motor behaviour. The connections which have been described between the nucleus accumbens and the caudate nucleus[25] and substantia nigra[25-27] might provide an anatomical basis for mesolimbic-nigrostriatal interactions such as those which we have described here. Finally, it is worthy of comment that this and previous work[8-15] emphasises a role of the mesolimbic dopamine system in motor function. Its pathology in motor dysfunction has very recently been reported (O. Hornykiewicz, unpublished).

Fusion of human erythrocyte ghosts promoted by the combined action of calcium and phosphate ions

CALCIUM ions are important in almost all membrane fusion systems[1,2]. Murayama and Okada[3] showed that Sendai virus-induced fusion of Ehrlich ascites cells required Ca^{2+}. When

Ehrlich ascites cells were treated with Sendai virus in the presence of EDTA, cells agglutinated and lysed but did not fuse[3,4]. Similarly, Ca[2+] was required for the fusion of erythrocytes stimulated by chemicals such as lysolecithin[5] or glyceryl monooleate[6]. Ca[2+] plus the ionophore A23187 (ref. 7) or Ca[2+] at high pH (ref. 8) promoted the fusion of chicken erythrocytes. Fusion of phosphatidylserine-rich liposomes was absolutely dependent on the presence of Ca[2+9]. We describe here the fusion of human erythrocyte ghosts promoted by the combined action of Ca[2+] and phosphate buffer. Human erythrocyte. ghosts, because they lack cytoplasm and are easily filled with small or large molecules[10,11] are useful for the investigation of membrane fusion.

calcium phosphate formed in the experimental conditions. In Tricine or Tris buffer plus Ca[2+] neither agglutination nor fusion was observed. To obtain fusion, it was essential to incubate the ghosts in phosphate buffer and then to add the Ca[2+]. If the Ca[2+] and the phosphate buffer were preincubated for 20 min at 37 °C before addition of erythrocyte ghosts, calcium phosphate precipitated. When ghosts were added to such a precipitate, there was some agglutination followed by lysis but no fusion. Calcium phosphate has been implicated in the facilitation of extracellular DNA .uptake in eukaryotic cells[13].

Table 2 shows the effects of changing the pH of the phosphate buffer on the agglutination and fusion of erythrocyte ghosts in

Table 1 Agglutination and fusion of human erythrocyte ghosts in presence of bivalent cations and various buffers

Experiment	Buffer	Salt	Concentration (mM)	Agglutination	Fusion
(1)	Phosphate	None			
	Phosphate	CaCl₂	2	+++	+++
	Phosphate	BaCl₂	2	+	+
	Phosphate	BaCl₂	4	++	++
	Phosphate	MnCl₂	2	++++	—
	Phosphate	ZnCl₂	2	++++	—
	Phosphate	MgCl₂	2	—	—
(2)	Phosphate	None		—	—
	Phosphate	CaCl₂	2	+++	+++
	Arsenate	None		—	—
	Arsenate	CaCl₂	2	—	Trace
	Tricine–NaOH	None		—	—
	Tricine–NaOH	CaCl₂	2	—	—
	Tris–HCl	None		—	—
	Tris–HCl	CaCl₂	2	—	—

Out-dated human blood type O was obtained from the blood bank of Hadassah Hospital, Jerusalem. Blood aged from 4–8 weeks was used (stored blood) In experiment (1) stored human erythrocytes were washed three times with a solution containing 150 mM KCl and 10 mM sodium phosphate buffer, pH 7.4 (isotonic solution) as described before[11]. To prepare ghosts, 2.5 ml of 25% (v/v) erythrocytes in the isotonic medium were dialysed for 2 h against 2 l of hypotonic medium containing 40 mM KCl and 10 mM sodium phosphate buffer, pH 7.4. Ghosts were resealed by adding 0.125 ml of a solution containing 2.2 M KCl and 0.02 M MgSO₄ and incubating them at 37 °C for 15 min. The ghosts were then washed three times in the isotonic solution. Erythrocyte ghosts were fused as follows. Reaction mixtures contained a final concentration of ghosts equivalent to 1.25% (v/v) of the original erythrocytes in a solution containing 120 mM KCl, 30 mM NaCl and 10 mM sodium phosphate buffer, pH 7.4. The experiment was initiated by adding bivalent metal ions as shown in the table and incubating the suspensions at 37 °C for 20 min. In experiment (2) erythrocyte ghosts were prepared as described for experiment (1) except that the phosphate buffer in the isotonic and hypotonic solutions was replaced where indicated by 10 mM Tricine–NaOH buffer, 10 mM Tris–HCl buffer or 10 mM sodium arsenate buffer, pH 7.4. Ghosts were fused as described for experiment (1). Agglutination and fusion were estimated by phase contrast microscopy. Agglutination: +, clump of 5–10 cells; ++, clumps of 10–20 cells; +++, clumps of 50–100 cells; ++++, big clumps of 100 cells or more. Fusion: +, fusion of two to four cells, and 5–10% of the ghosts fused; ++, polyghosts derived from 5–10 cells, and 10–20% of ghosts fused; +++, large polyghosts derived from 10–20 cells and 60–80% of ghosts fused

Table 1 shows the effects of various bivalent cations and different buffers on the agglutination and fusion of erythrocyte ghosts. Ca[2+] plus phosphate buffer was the most effective combination for promoting fusion. Ba[2+] (Table 1) and Sr[2+] (not shown) with phosphate buffer caused a moderate amount of fusion, and Ca[2+] and arsenate buffer caused a very small degree of fusion. Fusion was maximal with Ca[2+] and phosphate buffer after 15–20 min of incubation at 37 °C but the 'poly-ghosts' formed were unstable and disintegrated after a further 10–15 min. Ca[2+], Mn[2+], Zn[2+] and Ba[2+] agglutinated ghosts in the presence of phosphate buffer (Table 1). Zn[2+] and Mn[2+] in phosphate buffer did not promote fusion although they were active agglutinating agents. There seems to be a close correlation between the formation of a precipitate with phosphate ions and the agglutinating effect of bivalent cations. Mg[2+], the only cation tested which does not form a precipitate with phosphate, did not agglutinate ghosts. All bivalent metal ions which formed precipitates with phosphate caused agglutination. Fusion thus seems to be distinct from agglutination, and more specific in its bivalent metal ion requirement. Furthermore, in other experiments not shown here, ghosts agglutinated with Ca[2+] plus phosphate buffer disaggregated when titrated with acetic acid. The amount of acetic acid required for disaggregation was identical to that required to dissolve the precipitate of

the presence of Ca[2+]. Erythrocyte ghosts were agglutinated from pH 7.0 upwards; and fusion was maximal at pH 7.5. There was a direct correlation between the amount of calcium phosphate precipitated, which increased with pH, and the extent of agglutination.

Table 2 Effect of pH on agglutination and fusion of human erythrocyte ghosts by Ca[2+] plus phosphate

pH	Agglutination	Fusion	Remarks
5	—	—	
5.5	—	—	
6	—	—	
6.5	+	—	
7	++	+	Fusion after 60 min
7.5	+++	+++	Fusion after 20 min
8	++++	++	Fused cells disinte-
8.5	++++	+	grated shortly after
9	++++	+	fusion

Erythrocyte ghosts were prepared as described in Table 1 for experiment (1). Reaction mixtures contained a final concentration of ghosts equivalent to 1.5% (v/v) erythrocytes in a solution containing 120 mM KCl, 30 mM NaCl, and 10 mM sodium phosphate buffer, at the pH indicated. The experiment was initiated by adding CaCl₂ at a final concentration of 2 mM and the suspensions were incubated immediately at 37 °C for 20 min. Agglutination and fusion were estimated as described in Table 1.

Table 3 Effect of internal ATP on fusion of human erythrocytes or erythrocyte ghosts

Experiment	Cells	Treatment	Addition during fusion	Agglutination	Fusion
(1)	Fresh human erythrocytes	Stored at 4 °C	None	—	—
			2 mM CaCl₂	+ + + +	—
		Incubated at 37 °C with glucose, adenine, inosine and phosphate	None	—	—
			2 mM CaCl₂	+ + + +	—
		Incubated at 37 °C with NaF (ATP-depleted)	None	—	—
			2 mM CaCl₂	+ + + +	+ +
(2)	Human erythrocyte ghosts		None	—	—
			2 mM CaCl₂	+ + +	+ + +
	ATP-containing human erythrocyte ghosts		None	—	—
			2 mM CaCl₂	+ + +	—

In experiment (1), fresh human blood type O was used. ATP-depleted blood was prepared as described before[26]. The erythrocytes were washed in a solution containing 135 mM KCl, 5.4 mM NaCl, 0.8 mM MgSO₄ and 20 mM Tricine–NaOH, pH 7.4. Blood, 2% (v/v) was incubated overnight at 37 °C in the presence of 10 mM NaF for depletion of ATP or in the presence of 5 mM glucose, 10 mM adenine, 2 mM inosine and 5 mM sodium phosphate as a control. The samples were washed three times in a solution containing 120 mM KCl, 30 mM NaCl and 20 mM Tricine–NaOH, pH 7.4. Blood not incubated overnight was washed in the same solution. The three kinds of erythrocytes were suspended in the above solution at a concentration of 1.25% (v/v) in the presence of 2 mM CaCl₂ and 5 mM glucose (glucose was omitted in the depleted blood) for 30 min at 37 °C. The samples were then washed three times in a solution containing 120 mM KCl, 30 mM NaCl and 10 mM sodium phosphate buffer, pH 7.4, and suspended at a concentration of 2.5% (v/v). For fusion, CaCl₂ at a final concentration of 2 mM was added to each of the erythrocyte suspensions and they were transferred immediately to 37 °C for 20 min with slow shaking. Agglutination: + + + +, big clumps of more than 100 cells. Fusion: + +, polyerythrocytes made of 10–30 cells and 20–30% of the cells were fused. In experiment (2) stored human erythrocytes type O + were washed three times in a solution containing 160 mM KCl and 20 mM Tricine–NaOH, pH 7.4. Ghosts were prepared as follows: ATP was trapped in human erythrocyte ghosts by dialysis of 1.25 ml of 25% (v/v) of erythrocytes in the presence or absence of 5 mM ATP for 2 h, against 1 l of a hypotonic medium containing 40 mM KCl and 10 mM Tricine–NaOH, pH 7.4 at 0 °C. To 1 ml of each system of ghosts 0.050 ml of a solution containing 2.2 M KCl and 0.02 M MgSO₄ was added. The ghosts were resealed for 5 min at 37 °C then washed in a solution containing 150 mM KCl and 10 mM sodium phosphate buffer, pH 7.4 and suspended at a concentration equivalent to 25% (v/v) of the original erythrocytes. Fusion was achieved as described in Table 1, experiment (1). The cells were incubated at 37 °C for 30 min. Agglutination and fusion were estimated as described in Table 1, experiment (1).

Fresh human erythrocytes incubated with Ca^{2+} and phosphate buffer at pH 7.4 agglutinated but did not fuse (Table 3). It seemed possible that the failure of intact erythrocytes to fuse was attributable to the low concentration of internal Ca^{2+} maintained by their Ca^{2+} pump. Since depletion of ATP inhibits the Ca^{2+} pump which expels Ca^{2+} from the erythrocyte cytoplasm[13], the effect of ATP depletion on fusion was tested. Table 3 shows that ATP-depleted erythrocytes fused readily in phosphate buffer plus Ca^{2+}. The polyerythrocytes formed were unstable and disintegrated about 10 min after fusion. The inclusion of ATP in erythrocyte ghosts causes internal Ca^{2+} to be pumped out of them[14], so it was of interest to test the fusion of ghosts containing trapped ATP. Erythrocyte ghosts containing ATP agglutinated, but did not fuse, in conditions where ghosts without ATP fused freely (Table 3). These observations could be explained by assuming that fusion of erythrocytes or their ghosts requires intracellular Ca^{2+}. In earlier experiments, Ahkong et al.[7] showed that chicken erythrocytes, pretreated with neuraminidase, fused when Ca^{2+} was introduced to the cytoplasmic side of the membrane with cation ionophore A23187.

We have achieved fusion of human erythrocyte ghosts without the aid of virus, using Ca^{2+} and phosphate ions at a physiological pH and temperature. Previously, virus-induced fusion of human erythrocyte ghosts was observed only after gradual haemolysis in the presence of bovine serum albumin[15] or after drastic haemolysis followed by treatment with sulphydryl group-blocking agents[16].

Addition of Ca^{2+} to the medium causes the aggregation of intramembrane particles of human erythrocyte ghosts[17]. Presumably the Ca^{2+} penetrates to the cytoplasmic side of the membrane where it causes polymerisation of spectrin and consequent intramembrane particle aggregation[17]. It has been suggested that fusion of cells involves the rearrangement of intramembrane particles[18]. Because of the apparent interrelationships of Ca^{2+}, intramembrane particle rearrangement and

fusion, we used freeze-etching to investigate the distribution of intramembrane particles in ghosts fused with Ca^{2+} and phosphate ions. Figure 1a shows a section of erythrocyte ghosts fused with Ca^{2+} and phosphate ions. A polyghost agglutinated with unfused ghosts can be seen. Figure 1b shows a freeze-fracture picture of two cells whose membranes are in close juxtaposition. Most of the area of the inner phase of the membrane in both cells contains crowded intramembrane particles. The area of close contact of the two cells (arrow) is interesting in that it is almost devoid of intramembrane particles, and, there seems to be an interdigitation of membrane projections. It seems likely that this is an area of contact just before fusion.

Figure 1c is a freeze-fracture picture from a ghost preparation after fusion. The fracture face of the inner phase of the membrane consists of two areas studded with tightly packed intramembrane particles connected by a folded smooth area almost devoid of particles. It is tempting to suggest that the smooth area is a region of fusion joining two cells. No such smooth areas were detected in unfused controls. Since intramembrane particles are probably membrane proteins or glycoproteins, and fusion of cells has been suggested to occur between areas of exposed phospholipids[19], intramembrane particles might have been removed from regions in which fusion occurs. Previous work in our laboratory showed that on clustering of intramembrane particles, phospholipids are exposed and become susceptible to attack by chemical agents and phospholipases[20,21].

There are strong indications that Ca^{2+} is involved in certain biological processes involving membrane fusion such as secretion of macromolecules[22], endocytosis[23], fusion of myoblasts[24], and fusion of Golgi vesicles[25]. It is possible that fusion in these cases occurs by a similar mechanism to that suggested here.
Fig. 1 Electron micrographs of human erythrocyte ghosts in the process of fusing. Human erythrocyte ghosts were prepared and fused as described in the legend to Table 1, experiment (1). The bivalent metal used was CaCl₂ (2 mM). Samples were incubated for 25 min at 37 °C for fusion. Preparation of sections for electron microscopy (*a*) was as described before[27]. Freeze-fractured cells were prepared essentially as described before[20] with the following modifications. Erythrocyte ghosts were fixed immediately after fusion by addition of glutaraldehyde (Ladd Research Industries) to a final concentration of 1 % (v/v) and centrifuged at 12,000*g* for 5 min. *a*, Electron micrograph of a polyghost tightly agglutinated with unfused ghosts (× 4,800). *b*, Freeze-fracture picture of two cells tightly agglutinated before fusion. Interdigitated region of contact (arrow) is poor in intramembrane particles (× 38,280). *c*, Freeze-fracture picture of fused ghosts. Note folded smooth area separating surfaces with tightly packed intramembrane particles. The smooth area is presumed to be a region of fusion between two ghosts (× 61,200).

T lymphocytes with promiscuous cytotoxicity

CYTOTOXIC T lymphocytes generated during a unidirectional mixed lymphocyte culture (MLC) lyse target cells which have the antigenic phenotype of the allogeneic stimulating cells. The cytotoxic effect is restricted to cells that bear the same major histocompatibility antigens (H–2 antigens in mice) as the stimulating cells[1]. H–2 restriction of cytotoxicity is also seen when immune T lymphocytes react *in vitro* to cells bearing viral[2], chemical[3], or minor histocompatibility antigens[4] or following autosensitisation against unmodified fibroblasts[5]. Thus, H–2 restriction of cytotoxic lymphocytes has been observed in many circumstances. We now report that cultures of normal spleen cells generate T lymphocytes that damage target cells regardless of their H–2 phenotype.

To investigate the influence of alloantigens on the generation of cytotoxic T lymphocytes, we cultured normal mouse spleen in the presence or absence of allogeneic stimulator spleen cells or fibroblasts. After 5 d culture, the responder lymphocytes were tested against various fibroblast monolayer targets using a modification of a standard microcytotoxicity assay. In this system the number of adherent fibroblasts remaining after 48 h of incubation with the cultured spleen cells was measured by uptake of radioactive ⁵¹Cr. As seen in Table 1a, C57L (H–2ᵇ) spleen cells, after incubation with irradiated CBA stimulator cells (H–2ᵏ), caused fourfold greater cytotoxicity of B10.Br (H–2ᵏ) than C57BL/6 (H–2ᵇ) fibroblasts. This demonstrated the expected relative H–2 restriction of T-cell cytotoxicity which results from an allogeneic MLC. The presence of allogeneic fibroblasts also induced H–2-restricted cytotoxicity (Table 1b).

In contrast, spleen cells cultured alone, without allogeneic stimulator cells, showed a similar high degree of cytotoxicity against target fibroblasts without H–2 restriction (Table 1c). In each of 20 experiments, normal spleen cells cultured for 5 d developed promiscuous cytotoxicity that did not discriminate among the H–2 phenotypes of target fibroblasts.

To identify the effector cell in the population of cultured spleen cells, the influence of anti-θ treatment[6] was tested with the results shown in Table 2. The marked decrease of cytotoxic activity after anti-θ + C′ treatment suggests that a T lymphocyte was necessary for the expression of promiscuous cytotoxicity. This conclusion was supported by the finding that the cytotoxic effect was not decreased by filtering the effector cells through nylon wool. Thus, promiscuous cytotoxicity, like H–2 restricted cytotoxicity[7], seems to be a function of T lymphocytes. Cell-free medium

in which effector lymphocytes had been cultured for 48 h showed no cytotoxicity against target fibroblasts when compared with fresh medium. Therefore there was no evidence for a nonspecific cytotoxic factor produced by the lymphocytes.

Experiments were carried out to identify the requirements for induction of promiscuous cytotoxicity. Fresh spleen cells or spleen cells cultured for up to 48 h did not produce this effect. Cells cultured for 3 d had 50% of maximal cytotoxic activity. Peak activity was usually

*Suspension of spleen cells of 6–8-week-old male mice were prepared by forcing fragments of spleen through a tantalum gauze mesh. The spleen cells were suspended in medium consisting of RPMI 1640 (Grand Island, Gibco) plus 10% foetal calf serum (FCS) (heat inactivated at 56% for 30 min; Gibco), 5×10^{-5} M 2-mercaptoethanol, sodium pyruvate 1 mM (Microbiological Associates), non-essential amino acids 0.1 mM (Microbiological Associates) and penicillin (5,000 units ml^{-1}) and streptomycin (5,000 μg ml^{-1}) (RPMI + 10% FCS). The spleen cells were washed, centrifuged and resuspended at a concentration of 7×10^6 viable nucleated cells in 2 ml of RPMI + 10% FCS. The spleen cells were incubated for 5 d in 16-mm tissue culture wells (Costar) in a volume of 2 ml per well at 37 °C in moist air plus 10% CO_2. After induction the spleen cells were collected from the culture wells by repeated pipetting of the medium, washed by centrifugation and tested for cytotoxicity. Some induction cultures contained allogeneic stimulator cells which were either 3.5×10^6 irradiated (2,000 r.) spleen cells (*a*), or monolayers of 10^5 fibroblasts (*b*). The fibroblasts were prepared from 13–17-d-old mouse embryos as described[15].

†Cytotoxicity was assayed in quadruplicate by incubating test spleen cells with target fibroblasts at effector–target ratios of either 50:1 or 100:1. Control cultures contained fresh uncultured spleen cells of the same genotypes as the test spleen cells. One million spleen cells in 2 ml RPMI + 10% FCS were added to either 10^4 or 2×10^4 target fibroblasts which had been cultured for one day in 16-mm culture wells. After 44 h, the spleen cells and detached fibroblasts were aspirated and the adherent fibroblasts washed four times with RPMI × 10% FCS. To measure the relative numbers of adherent fibroblasts, we incubated each culture well for 40 min with 3 μCi ^{51}Cr in 0.2 ml of 0.3 M sucrose. The wells were then washed twice with RPMI + 10% FCS and aspirated dry. Uptake of ^{51}Cr was determined by digesting the fibroblasts with 1 ml 0.1 N NaOH. After 30 min the contents of each well were transferred to plastic tubes and radioactivity was measured in gamma counter. Percentage cytotoxicity was computed as (1−mean c.p.m. (target with test spleen cells/target with control fresh spleen cells) × 100). The standard deviations were always less than 10% of the mean c.p.m.

attained after 4–5 d of culture and persisted undiminished for up to 9 d.

Adherent cells such as macrophages are involved in the induction of cytotoxic T lymphocytes by allogeneic cells[8]. The role of an adherent population in the induction and effector phases of promiscuous cytotoxicity was investigated with the results shown in Table 3. Spleen cells were plated on Petri dishes for 1 h at 37 °C. The non-adherent cells were removed, cultured alone for 5 d and then assayed for cytotoxicity. The non-adherent cells had a markedly decreased capacity to generate cytotoxic cells when compared with an unseparated population. Conversely, absorption of spleen cells on Petri dishes after 5 d of culture did not reduce their capacity to mediate cytotoxicity. Fractionation of spleen cells on nylon wool columns before or after *in vitro* culture confirmed the requirement for an adherent cell in the induction of cytotoxicity, but not in the effector phase.

The inducer of promiscuous cytotoxicity is unknown. Foetal calf serum in the culture medium might have contained mitogen-like substances capable of inducing polyclonal differentiation of effector lymphocytes[9]. It is also

Table 2 Effect of anti-θ treatment on promiscuous cytotoxicity

Treatment of C57BL/6 cytotoxic spleen cells	% Cytotoxicity of C57BL/6 fibroblast targets
None	94
C′	91
Anti-θ	93
Anti-θ + C′	33

Promiscuous cytotoxicity was induced and tested as in Table 1. After induction, the spleen cells were untreated, or treated with complement (C) anti-θ globulin or anti-θ globulin + C′ and tested for cytotoxicity against syngeneic fibroblasts (see Table 1). Anti-θ globulin (Cohn Fr. II of AKR anti C3Hθ serum) was added to spleen cells (30×10^6–50×10^6) at a dilution of 1:10 in 0.3 ml and incubated at room temperature for 45 min. C′ (fresh guinea pig serum absorbed with C57BL/6 spleen cells for one hour at 0 °C) was used at a final dilution of 1:9 in 1 ml and incubated at 37 °C for 1 h. Some spleen cells were treated sequentially with anti-θ globulin followed by C′.

possible that the foetal calf serum was specifically immunogenic during induction. Its association with the fibroblasts in the target cultures could therefore have triggered cytotoxicity to the fibroblasts[10]. This is unlikely, however, since we found that adding either allogeneic or syngeneic fibroblasts to the inducing cultures led to H-2 restriction of the resulting cytotoxicity (our unpublished results).

Regardless of the underlying mechanism, it is clear that *in vitro* culture of spleen cells can lead to the generation of T lymphocytes with relatively unrestricted cytotoxicity. How then does addition of allogeneic cells to the culture abort promiscuous cytotoxicity? It is possible that the relevant alloantigens may favour the selective proliferation of clones. Alternatively, the induction of specific cytotoxicity by allogeneic cells may be accompanied by the active suppression of unselected clones.

The emergence of nonspecific suppressor activity following *in vitro* culture of normal spleen cells has been observed by Hodes and Hathcock[11] and by Burns *et al.*[12]. "Precultured" spleen cells could not be induced into cytotoxic effectors in an MLC. Such cells also suppressed the responses of fresh spleen cells to allogeneic or modified syngeneic targets[11]. The induction of antibody production *in vitro* was also inhibited by spleen cells cultured in a similar manner[12]. This suppression was mediated by a T lymphocyte and had similar kinetics and cellular requirements for induction as the promiscuous cytotoxicity reported here.

What is the relationship between promiscuous cytotoxicity and the reports of suppressor activity that developed spontaneously in cultures of mouse spleen cells? These

Table 3 Effect of removal of adherent cells on promiscuous cytotoxicity

After induction	70

Promiscuous cytotoxicity was induced and tested as in Table 1. Some of the spleen cells were absorbed before induction by placing 20×10^6 cells in 3 ml RPMI + 10% FCS in 60-mm tissue culture dishes (Falcon) and incubating at 37 °C for 1 h. Non-adherent cells were removed by repeated pipetting, cultured for 5 d and tested for cytotoxicity. Some spleen cells were cultured for 5 d and then absorbed as above. The non-adherent cells were then tested for cytotoxicity.

phenomena conceivably result from activities of distinct subclasses of T lymphocytes: cytotoxic and suppressor cells. Alternatively, these phenomena may reflect the dual function of a single subclass of lymphocytes. In other words, these different *in vitro* measurements may be manifestations of the same biological function. Suppression of an MLC or antibody production[11,12] could result from indiscriminate damage to the reacting lymphocytes. And the effect we observed may be yet another manifestation of suppressor cell function. Identity of suppressor and cytotoxic T lymphocytes is also supported by the finding that the cells mediating these activities share the same Ly-2,3 T-cell marker[13,14].

New principle for the analysis of chemical carcinogenesis

THE development of cancer following exposure to chemical carcinogens or to various forms of irradiation is almost invariably slow and prolonged. Although the process can be initiated by a brief exposure to a carcinogenic stimulus, there is no evidence that target cells so altered are cancer cells. Rather, there is abundant indirect evidence from many systems that what is induced is an altered cell or cell population from which malignant neoplasia can gradually develop or evolve[1,2]. Neoplastic development therefore resembles a chain reaction, triggered by exposure to a carcinogen, in which the links are new populations with altered organisational, structural and biochemical properties. These slowly proliferative new lesions are characteristically focal in distribution, implying that only a small proportion of the original target cell population in any organ or tissue participates. It is not known what the critical property (or properties) is that makes initiated cells so important in carcinogens and the failure to understand and manipulate this early step has been a major impediment to its analysis.

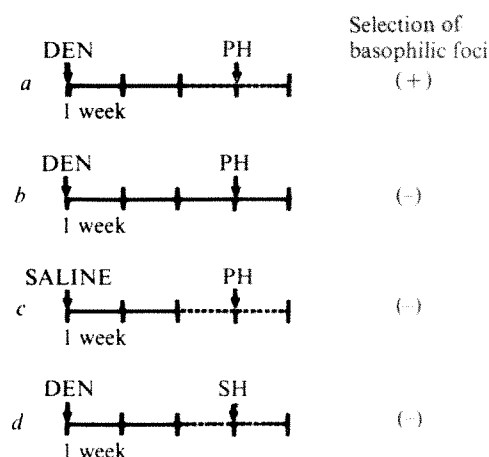
We have developed a new approach to the study of chemical carcinogenesis which seems to offer the first quantitative assay for populations of initiated cells, as well


Fig. 1 Schematic representation of the assay procedure (*a*) for initiated cells in liver induced by a carcinogen. *b*, *c*, *d*, Essential controls. DEN, 200 mg per kg body weight intraperitoneally; —, 1 week of basal diet; – – –, 1 week basal diet plus 0.02% AAF; PH, partial hepatectomy; SH, sham hepatectomy.

as the possibility of a sequential analysis of some of the early putative preneoplastic and premalignant hepatocytes for liver cancer. The principle is functional rather than morphological or biochemical and depends on the increasing evidence that the selective growth of focal precancerous liver cells seems to result from their relative resistance to the cytotoxic action of hepatocarcinogens, coupled with the creation of a local environment for their proliferation.

All known hepatocarcinogens inhibit regeneration of liver cells following partial hepatectomy and at higher doses may lead to liver-cell death. The focal, slowly proliferative cell populations called hyperplastic nodules, that occur in the liver before the appearance of cancer, all acquire new properties relating to the metabolism and toxic effects of hepatocarcinogens and other hepatotoxins that require metabolic activation. These include resistance to hepatotoxin-induced cell death[3], decreased uptake and/or activation of some carcinogens[3], a uniform decrease in several components of microsomal mixed function monooxygenase system including cytochrome $P450$, aryl hydrocarbon hydroxylase and aminopyrine demethylase[4,5] and also the capacity for proliferation following partial hepatectomy during carcinogen administration[6,7].

In the light of these considerations, we wondered

whether an early, or even first, change induced by an hepatocarcinogen might be the induction of an altered metabolic pattern in some liver cells (similar to that seen in hyperplastic nodules), such that these cells would have a potential growth advantage over the majority of original hepatocytes in a cytotoxic environment. If this were the case, it should be possible to detect the altered cells soon after initiation by creating an intense stimulus for proliferation in the presence of a toxic growth inhibitor requiring metabolic activation. Initiated cells with a decreased capacity for activation might proliferate rapidly, whereas cells unaltered in this respect would activate the carcinogen and thereby generate a derivative which would inhibit their proliferation. On the basis of this theory, we devised an assay system for such resistant cells (Fig. 1a).

The assay system consists of three components: an initiator, for example, diethylnitrosamine (DEN); a selective growth inhibitor, 2-acetylaminofluorene (2-AAF), and a generalised potent growth stimulus, in this case, partial hepatectomy (PH). The major carcinogen so far studied has been DEN, since it can induce liver cancer in the rat slowly with a single oral, intravenous, or intraperitoneal administration[8,9]. DEN was given intraperitoneally to Fischer-344 rats at a dose of 200 mg kg^{-1}. Following a 2-week period of recovery from the initial cell damage, the animals were fed a standard basal diet (24% protein) containing 0.02% 2-AAF for 1 week and were then subjected to 67% partial hepatectomy. With only 2-AAF and partial hepatectomy, there was no hepatocyte proliferation, and no labelling of hepatocyte nuclei with ^{3}H-thymidine as observed autoradiographically. In animals pretreated with DEN, however, there were multiple focal islands of proliferating intensely basophilic hepatocytes (Fig. 2) distributed randomly throughout the liver which started to appear about 30 h after operation. They grew rapidly, so that within 7–10 d they are visible grossly as small, greyish-white nodules about 1 mm in diameter. No such foci were seen in animals treated with saline in place of DEN, given 2-AAF without PH, subjected to PH without concomitant exposure to 2-AAF or subjected to sham operation. Although subsequent studies have shown that feeding the 2-AAF diet for about 3 weeks before PH is sufficient to induce a few basophilic foci, they were rarely seen in the present experiments without pretreatment with DEN.
The number of foci induced by DEN varies with the dose. Figure 3 shows the relative 'focus-forming ability' over a dose range of 20 to 200 mg kg^{-1}. The foci could be counted either by low power examination of histological sections (Fig. 2) or at 7–10 d by counting the foci in a gross liver section, the sections of liver having been taken from a standard site. Foci similar to those seen with DEN have been induced by every hepatocarcinogen studied to date, including dimethylnitrosamine, aflatoxin B1, and N-hydroxy-2-AAF.

The initiated foci can be labelled with ^{3}H-thymidine without labelling the surrounding original hepatocytes and

in this way, the fate of the hepatocytes in the foci can be followed. If the dietary 2-AAF is discontinued following partial hepatectomy, selective proliferation of the foci stops as the majority of original hepatocytes recover the ability to proliferate. By manipulating the conditions, it thus becomes possible to control the number of cell proliferations and to study their role in the development of cancer.

Following termination of the specialised regimen at 7 d after operation, the foci continue to grow, so that by 8 weeks the liver is composed of many hyperplastic nodules indistinguishable from those described previously[10,11]. If the animal is not subjected to the 'selection pressure' used (2-AAF plus PH), the latent or potential foci persist for at least 10 weeks without any significant change in size or number. Thus, the initiated hepatocytes induced by DEN have not yet acquired the property of autonomous growth but can be induced to grow in an appropriate environment. Also, we have obtained no evidence for their recognition by the host or for their removal or repair. The later development of some autonomous growth of such cells represents another step in the sequence before the ultimate development of malignant neoplastic cells.
Fig. 3 Induction of foci of initiated liver cells as a function of the dose of diethylnitrosamine (DEN). The number of foci was counted in sections from each lobe by low power microscopy and is expressed per cm^2 of cross-sectional area (mean ± s.e.m.).

Scherer and Emmelot detected histochemically and counted microscopic foci of enzyme-deficient hepatocytes induced with DEN[12]. These foci may prove to 'be the initiated populations selected in the present system.

The interval between the administration of carcinogen and the assay is being shortened so that the kinetics of induction of the initiated foci can be established clearly with different carcinogens. Another desirable modification would be the use of a non-carcinogen as the selective growth inhibitor. Even in its present form, however, the assay is useful for the study of several aspects of chemical carcinogenesis, including the possible role of DNA synthesis and of repair of specific DNA damage in initiation, the persistence of initiated cells, the sequential analysis of the properties of hepatocytes acquired after initiation, the possible functional theme underlying the development to liver cancer and the clarification of some confusing aspects in the use of liver hepatoma formation in mice as an assay for carcinogens.

The hypothesis of differential cytotoxicity as an important theme for chemical carcinogenesis is not new[4,10,13–17], but it has never been subjected to critical tests. On the basis of our results, it is tempting to consider that the acquisition of resistance to some of the toxic effects of an added carcinogen or, in the case of a single exposure to a carcinogen, to toxic xenobiotic compounds in the natural

diet or absorbed bacterial products in the intestinal tract, may be the major motive force during liver carcinogenesis until the precancerous cells can grow autonomously. Consistent with this view of liver carcinogenesis are the findings of Peraino and colleagues on the acceleration of liver carcinogenesis by phenobarbital or DDT in animals exposed for only 18 d to 2-AAF (refs 18, 19). An underlying hypothesis for liver carcinogenesis is now developing, which is amenable to experimental tests. Whether the principle of selective cytotoxicity can be extended to the development of cancer in other organs or tissues remains to be explored.

Ammonia assimilation in lupin nodules

ROBERTSON *et al.*[1,2] proposed that plant enzymes rather than bacteroid enzymes are physiologically important in the assimilation of the ammonia produced after nitrogen reduction in the bacteroids of leguminous nodules. They demonstrated that during the development of the nodule, glutamine synthetase (EC 6.3.1.2, equation (1)) and glutamate synthase (EC 2.6.1.53, equation (2)) activity increased considerably in the plant fraction but not in the bacteroid fraction of the nodule, parallel with the induction of nitrogenase and leghaemoglobin.

$$\text{glutamate} + NH_4^+ + ATP \longrightarrow \text{glutamine} + ADP + P_i \quad (1)$$

$$\text{glutamine} + \text{2-oxoglutarate} + NADH$$
$$\longrightarrow \text{2 glutamate} + NAD^+ \quad (2)$$
But, the predominant amino acid transported in the xylem of lupins and many other legumes is asparagine[2–4]. Robertson *et al.*[2] suggested therefore that asparagine was most probably synthesised in the plant fraction of the nodule by a glutamine-dependent asparagine synthetase[5,6] (EC 6.3.5.4, equation (3)) rather than in the bacteroids, which might utilise for asparagine biosynthesis an ammonium-dependent asparagine synthetase

(EC 6.3.1.1, equation (4)), which has been reported to occur in other prokaryotes[7].

$$\text{aspartate} + \text{glutamine} + ATP \longrightarrow \text{asparagine}$$
$$+ \text{glutamate} + AMP + PP_i \quad (3)$$

$$\text{aspartate} + NH_4^+ + ATP \longrightarrow \text{asparagine} + AMP + PP_i \quad (4)$$
We now report the formation of asparagine by a cell-free extract of the plant fraction of lupin nodules in the presence of ATP, aspartate, glutamine and Mg^{2+} (Table 1). Apparent K_m values for aspartate and glutamine were determined to be 3.6 mM and 0.26 mM, respectively. Ammonia could replace glutamine as the source of the amide nitrogen; but a fourfold greater concentration of ammonia gave only a rate of synthesis half that observed with glutamine (Table 1). Asparagine synthetase activity could not be detected unless the nodules were crushed in the presence of a sulphydryl protecting agent such as dithiothreitol. Furthermore, the enzyme was found to be stabilised by inclusion of 5 mM glutamine or 6 mM 5-diazo-4-oxo-L-norvaline (DONV), a glutamine analogue in the buffer. These properties of the asparagine synthetase from the plant fraction of *Lupinus angustifolius* nodules are in good agreement with the properties of the enzyme recently purified from etiolated *Lupinus luteus* cotyledons[8].

Asparagine synthetase activity in the plant fraction of the developing nodules was first detected 13 d after the seedlings were inoculated with rhizobia (Fig. 1). The rapid increase in activity seen after day 13 is similar to that already reported for the plant glutamine synthetase (ref. 1 and repeated here Fig. 1), plant glutamate synthase[2], nitrogenase[1] and leghaemoglobin[1]. No asparagine synthetase activity could be detected in the plant fraction of 11 or 12-d-old nodules (Fig. 1). But these fractions contained an asparaginase activity whereas the plant fractions from 13-and 24-d-old nodules did not (Fig. 1). Attempts to detect asparagine synthetase activity in the plant fraction of 11-and 12-d-old nodules in which the asparaginase was inhibited 80–90% with DONV (a known inhibitor of bacterial asparaginases[9]) were unsuccessful (Fig. 1).

Table 1 Synthesis of asparagine by extracts of the plant fraction of lupin nodules

Incubation mixture	Asparagine synthetase activity (nmol asparagine per min per mg protein)
Complete system	2.33
−glutamine	0.30
−glutamine + 13.2 mM NH_4Cl	1.23
−Mg^{2+}	ND
−ATP	ND
Boiled enzyme	ND

Lupins (*Lupinus angustifolius* L. var. Uniwhite) were inoculated with *Rhizobium lupini* (NZP 2257) and grown in a controlled environment cabinet[2]. Nodules were collected from 25-d-old plants, crushed in 0.5 M sucrose, 50 mM K phosphate buffer, *p*H 7.8, containing 5 mM dithiothreitol and separated into a bacteroid and plant fraction as previously described[2]. Asparagine synthetase activity was measured at 30 °C by the formation of ^{14}C-asparagine in a total volume of 300 µl containing plant fraction (200 µl), 4 mM L-4-^{14}C-aspartate (0.83 µCi µmol⁻¹), 3.3 mM $MgCl_2$, 3.3 mM L-glutamine and 4 mM ATP. Samples of 25 µl were removed during 15 min of incubation and applied to a Whatman 3 MM paper. Asparagine was separated from aspartate by electrophoresis at *p*H 5.0 and the radioactivity in each amino acid was determined[1]. Identification of the product as asparagine was confirmed by electrophoresis and chromatography using two procedures: (1) electrophoresis in formic acid–water (4% v/v) adjusted to *p*H 2.2 with pyridine (50 V cm⁻¹ for 2 h) followed by descending chromatography in *n*-butanol–*n*-butyl acetate–acetic acid–water (19:1:5:25 v/v) and (2) electrophoresis in 0.04 M sodium acetate, *p*H 5.0, (30 V cm⁻¹ for 30 min) followed by descending chromatography in methanol–pyridine–water (80:4:20 v/v). Furthermore, the ^{14}C-asparagine eluted from these chromatograms was converted to ^{14}C-aspartic acid by hydrolysis in 2 M HCl at 105 °C for 16 h.
ND, not detectable, less than 0.2 nmol per min per mg of protein.

The decrease in asparaginase activity in the plant fraction at days 11 and 12 coupled with the complete absence of this enzyme on day 13 (Fig. 1) was particularly interesting. This plant asparaginase was different from the bacteroid or free-living rhizobial enzyme in terms of (1) electrophoretic mobility on 7.5% polyacrylamide gels relative to bromophenol blue (0.47 for the plant enzyme and 0.27 for the bacteroid or rhizobial enzyme) and (2) apparent K_m for asparagine (7 mM for the plant enzyme and 6 μM for the rhizobial enzyme). In view of the fact that the plants were grown in a nitrogen-free medium, it seemed likely that until the bacteroids developed nitrogen-fixing ability, the plant asparaginase had a role in supplying the developing nodule tissue and bacteroids with ammonia by hydrolysing asparagine transported from the cotyledons. Once nitrogen fixation had been established 11–12 d after inoculation the plant asparaginase would no longer be required and activity would be lost (Fig. 2). An analogous role for a plant asparaginase in supplying rapidly developing legume seed tissue with C and N has been proposed by Atkins *et al.*[10].

So far we have been unable to detect any ammonium- or glutamine-dependent asparagine synthetase activity in either the bacteroid fraction of the nodules or in cell-free extracts of the free-living rhizobia grown in a broth or minimal medium. Attempts were made to inhibit or remove an asparaginase activity from these extracts before assaying for asparagine synthetase, but in no case could any synthetase activity be detected.

Our studies reported here and elsewhere[1,2] have led us to suggest that plant enzymes rather than bacteroid enzymes are involved in the assimilation of the ammonia produced from nitrogen reduction in the bacteroid. The first step in this assimilation (Fig. 2) is proposed to be the synthesis of glutamine by the plant glutamine synthetase. It has been estimated previously[2] that the levels of this enzyme found in the plant fraction of the nodule would be able to incorporate into glutamine more than twice the amount of ammonia actually produced by the bacteroids in 18-d-old lupin nodules. On the other hand,

Fig. 2 Proposed pathway for the assimilation of the ammonia produced after nitrogen reduction in the bacteroids into asparagine by enzymes located in the plant fraction of lupin nodules.

less than 3% of this ammonia could be assimilated by the bacteroid enzyme[2], a conclusion recently confirmed by the work of Kurz *et al.*[11] and Brown and Dilworth[12]. The high level of this plant glutamine synthetase, reported here in lupin and in other legume nodules[12], coupled with the low K_m for NH_4^+ (0.02 mM)[13] would provide an efficient mechanism for rapidly removing any ammonia passing out of the bacteroid into the plant. In the presence of this enzyme it is unlikely therefore that the plant asparagine synthetase would be able to incorporate ammonia directly into asparagine since the K_m for NH_4^+ for the plant asparagine synthetase is 3–5 mM (refs 5 and 6).

After the incorporation of ammonia into glutamine in the plant fraction of the nodule tissue, the amide nitrogen of glutamine would according to our model be transferred through glutamate using glutamate synthase and a transaminase to oxaloacetate to give the α-amino of aspartate (Fig. 2). The synthesis of asparagine by the glutamine-dependent asparagine synthetase would then be accomplished using this aspartate and a second amide nitrogen from glutamine (Fig. 2). The net result of these reactions would be the synthesis of asparagine from oxaloacetate and 2 mol of ammonium requiring NADH and 3 ATP.

The role of asparagine as the major amino acid carrier of fixed nitrogen is supported by an examination of the amino acid

Fig. 1 Levels of asparagine synthetase, asparaginase and glutamine synthetase during nodule development in lupin. Nodules were collected from plants collected at intervals after inoculation and the plant enzyme fraction was prepared as in Table 1. Asparagine synthetase activity was assayed as for Table 1 (●) or after DONV treatment[2] (○). Glutamine synthetase levels (■) were determined as previously described[1]. Asparaginase activity (□) was determined radiochemically using the procedure outlined for glutaminase assays[1], except that ^{14}C-U-asparagine was used as substrate instead of glutamine.

Table 2 Amino acid analysis of xylem sap from 11- and 18-d-old lupin plants

Amino acid*	μmol amino acid per ml per sap	
	11 d	18 d
Asparagine†	0.77	2.35
Aspartate	0.32	0.54
Glutamine†	0.23	0.41
Glutamate	0.33	0.36
Threonine	0.15	0.40

Xylem sap was collected using a pressure chamber[11] and stored under liquid nitrogen. Amino acid analyses were carried out using a JEOL 6A-H analyser.

*The level of all other amino acids was less than 0.1 μmol per ml of sap.

†Determined as the increase in aspartate or glutamate on hydrolysis for 4 h at 105 °C in 1 M HCl.

levels in the xylem sap of 11- and 18-d-old plants (Table 2). Although asparagine is the predominant amino acid transported in both cases, it is the asparagine level which increases and not that of glutamine as the capability of the nodule to fix nitrogen increases. Transpiration rates determined using 18-d-old plants were such that the plants would be transporting asparagine at a rate of 2 µmol per h per plant. Furthermore, we can estimate from the activity of asparagine synthetase reported here, that the nodules could synthesise up to 0.8 µmol asparagine per h per plant, which is in reasonable agreement with the rate of transportation of this amide considering the instability of asparagine synthetase *in vitro*.

In conclusion, we have proposed a pathway by which ammonia produced by the bacteroids is assimilated by the plant fraction of lupin nodules. Presumably the bacteroid enzyme systems provide the ATP and electrons for N_2-reduction whereas the plant enzyme systems provide the additional NADH and ATP required for the incorporation of ammonia into asparagine. Further interest will undoubtedly lie in elucidating the mechanisms regulating the synthesis of nitrogenase in the bacteroids, and leghaemoglobin, glutamine synthetase, glutamate synthase and asparagine synthetase in the plant fraction of the nodule. The regulation of the plant asparaginase activity and the reason why the bacteroids overproduce ammonia for plant growth beyond the level required for bacterial growth are also intriguing questions demanding further study.

Submarine pollination in seagrasses

THERE is great interest in water plants and their adaptation to the aquatic environment. Seagrasses, in the family Cymodoceaceae, are the only wholly marine group of flowering plants which carry out their entire life cycle in the sea[1]. The male and female flowers are borne on different plants. Consequently, their pollination mechanism presents intriguing problems, for terrestrial angiosperms, from which seagrasses presumably arose[2,3], shed dry pollen. This becomes hydrated only after alighting on the female stigma, where recognition events determine acceptance or rejection of the pollen[4]. These events seem to involve interactions between surface proteins or glycoproteins borne by both pollen and stigma[5]. The pollen proteins are released on to the stigma during normal pollination[6,7], but are lost from the surface whenever pollen is wetted[8]. The system found

in terrestrial species could thus hardly operate with submarine pollination. We have found that adaptations have occurred in both pollen and stigma of the seagrasses, accommodating the pollination system to the marine environment. Changes in the shape and form of the pollens, together with the loss of the outer wall layer, make it possible for the pollen to be carried in water currents as long, rope-like masses. The receptive stigma cells secrete a proteinaceous surface layer that is not dispersed in seawater, providing a suitable medium for trapping the pollen during submarine pollination.

We have used two species of sea nymph, *Amphibolis antarctica* and *A. griffithii*, found only on the temperate southern coast of Australia, and *Thalassodendron ciliatum*, widely distributed in tropical parts of the Indo-Pacific region, collected in Madagascar and Mauritius. No significant facts on the nature of their reproductive structures have been published since the pioneering studies of Ascherson[9] and Black[10], reviewed by den Hartog[3]. We have found in both genera that flowering occurs in early summer, and the plants are dioecious with separate male and female individuals. The flowers are hidden within the leaf sheaths. The paired anthers (Fig. 1a) extend upwards by peduncle elongation at maturity, when the entire structure is abscinded and floats free at the time of anther dehiscence. The female flowers remain hidden, the filamentous stigma branches elongate when receptive and protrude between the leaf sheaths (Fig. 2a).

The pollen grains are remarkable. They are elongate and confervoid, each more than 6 mm long, non-aperturate and at maturity they are coiled like a spring within the anther (Fig. 1b). They are trinucleate, with the nuclei located
Fig. 1 Male flowers of the sea nymph, *Amphibolis antarctica*. *a*, Male inflorescence consisting of paired anthers fused to form a single dispersal unit (×4). *b*, Scanning electron micrograph of anther freeze dried at dehiscence, showing release of coiled pollen grains (×45). *c*, Vermiform pollen grains dehiscing from anther into seawater, revealed by the fluorochromatic reaction[19], a test for pollen viability. The cytoplasm of the grains shows intense green fluorescence (×80).

centrally. The walls are unusual in apparently having no outer exine, which in terrestrial plants is made of the polymer sporopollenin[11]. Cytochemical tests have revealed no trace of exine. In transverse sections, the walls of mature pollen stain a uniform red colour with toluidine blue, like the inner intine layer of terrestrial angiosperm pollens. Microspectrophotometric analysis of the red stain has revealed only the 565-nm peak characteristic of the intine, and not those of the green-stained exine (590 and 640 nm) of the terrestrial plants; fluorescence microscopy after staining with 0.01% auramine O at pH 5.0, which provides even higher resolution, has revealed absence of the yellow fluorescence characteristic of the exine (personal communication from J. Heslop-Harrison). Transmission electron microscopy of other aquatic plants[12] has demonstrated a progressive loss of exine, though in no case was it absent.

The grains adhere together, forming a rope-like structure when teased from a mature anther into seawater (Fig. 1c). The pollen is soft and flexuous, bending in water currents as it escapes from the anther. The surface appears smooth under scanning electron microscopy, and a faint reticulate pattern is evident at higher magnification. The tips of the grains grade into a pair of fine, curved hooks, which presumably enable the pollen grains to link together on dehiscence and to attach to the smooth stigma surface. As well as these adaptations to the marine environment, seagrass pollen has some features in common with land plants[13]. Seagrass pollen walls contain cytochemically-detectable acid phosphatase activity, except that the enzyme reaction product is distributed throughout the wall instead of being confined to the inner intine layer. Furthermore, esterase activity, usually restricted in terrestrial plants to the outer exine layer[14], occurs on the surface of the grains in immature anthers associated with the invasive tapetum but is absent in mature pollen.

In both genera, the paired female flowers each have a style bearing several stigma branches. The tips are coated, when receptive, with a surface layer which can be detected cytochemically by its esterase activity (Fig. 2b). Such layers are characteristic of both wet and dry stigmas of land plants, and have been implicated in pollen recognition[15,16]. In terrestrial species, the layer can be partially solubilised in buffer and detergent[5]. In *Amphibolis*, however, the esterase activity of the coating does not disperse readily in seawater. In stigma sections, enzyme reaction product is present in the outer walls of the epidermal cells which correspond to the papillae of terrestrial plants and in the extra-cuticular layer secreted from the cells on the surface (Fig. 2c).

Fertile fruits of *Amphibolis* are frequent, so that communication between the pollen released into the sea from male flowers and the stigma does indeed occur. Pollination takes place when the plants are totally submerged, and must involve unique adaptations for cell recognition. The surface of the flexuous pollen grains is adhesive, suggesting the presence of a coating, possibly glycoprotein in nature, that is either resistant to the solubilising action of seawater, or constantly being secreted from within the grains. Arabinogalactan proteins are secreted in large quantities into the medium from *Lolium multiflorum* endosperm cells in liquid culture[17], suggesting that such a mechanism is not without precedent.

Both *Amphibolis* and *Thalassodendron* are viviparous[3] and the single basal embryo develops directly into a plantlet. After fertilisation, special floral structures differentiate to enable the seedling to find a foothold on the sea bed. Vivipary of this kind is also found in other intertidal plants like mangroves and the monocotyledon *Cryptocoryne*[18].

We believe that the features we have described are those of a group of angiosperms that has adapted successfully to the marine environment by the loss or modification of terrestrial features.

matters arising

Nucleosynthesis and anomalous Xe and Kr in carbonaceous chondrites

BLACK[1] has suggested that the anomalous Xe isotopic composition known as carbonaceous chondrite fission (CCF) Xe results from a varient of the r-process and is not due to fission. To yield the CCF Xe isotopic composition, the r-process peak due to the neutron magic number 82 would need to occur at mass 136 rather than 130 as in standard Solar System material[2].

An actual r-process scenario has two difficulties. First, r-process calculations yield an abundance peak far too steep compared with the CCF data, when the abundance peak occurs close to the magic number on the valley of β stability (for the magic number N =82, β stability is at mass 138). Second, the time scale of an r-process resulting in a peak within two mass units of β stability is very long compared with that of an exploding object (the r-process time scale is determined by the β rates, which are relatively long near the valley of β stability); thus there is no plausible astrophysical site.

Another closely related possibility exists: a neutron capture process much faster than an s-process but operating under the same principle of competition between neutron capture and β decay. We have prepared a computer program to carry out such generalised neutron capture (n-process) studies[3]; the neutron capture cross sections required by the program code are derived from the Hauser–Feshbach code of Holmes et al[4]. This n-process may occur in novae, supernovae shocks or in explosive supernovae shells.

We have examined the predicted Xe and Kr relative (heavy) isotopic abundances as a function of neutron flux for neutron temperatures of 2–155 keV (Fig. 1). Also shown in Fig. 1 are the recent Allende experimental results of Anders et al[5,6] and the implied heavy Xe spectrum for Murchison[7] after a large fractionation correction (the nonfractionation corrected Murchison heavy Xe spectrum looks like the Allende heavy Xe spectrum). All other proposed heavy Xe spectra lie somewhere between these two curves. It is not possible to get a good fit for either the Anders et al. unfractionated Xe or the Kr data and, furthermore, the best

Fig. 1 The calculated isotopic abundances of Kr and Xe as a function of neutron flux. Also shown are Allende experimental results of Lewis et al[6] and the Murchison Xe results of Srinivasan et al[7] with their large fractionation correction. The calculations may fit the Murchison xenon results but they cannot fit the Lewis et al[6] Kr results, nor a heavy Xe spectrum with a large dip at 132. ●, Allende; ■, Murchison; neutron flux on an arbitrary scale: □, 1; ◇, 30; ○, 70; △, 300.

fit for each does not occur for the same flux. These results are for 155-keV neutrons, similar results obtain at other neutron energies down to 2 keV. Near β stability the cross section computer code is good to a factor of order two (S. E. Woosley, personal communication); greater changes in neutron cross sections would be needed and specifically selected to get a good fit to the unfractionated Allende results. Such a selected set of cross section changes is not likely. Note, however, that the heavy Xe spectrum corrected for a large implied fractionation is not very different from a possible n-process. If further experimental work indeed shows the carbonaceous chondrite heavy Xe spectrum to be relatively smooth without a dip at 132, then perhaps the results can be explained with some sort of an n-process. Unfortunately, the Kr results cannot be fitted, but they are probably less reliable than the Xe results (E. Anders, personal communication). If the heavy Kr spectrum of Anders et al. is verified then a steady-state n-process explanation is no longer possible.

There is another important point with regards to the Allende xenon results of Anders et al[5] and Lewis et al[6]. Pepin[8] has pointed out that enriched light Xe isotopes seem to be a separate component from the heavy isotopes. From examination of the relevant nuclear processes, it seems clear that the light Xe anomalies cannot be fitted with spallation reactions —such reactions always produce $^{126}Xe > ^{124}Xe$ for any plausible seed distribution. Perhaps the explanation of the anomalous light isotopes lies in either the p-process[9] or in fractionation[10]. If the light xenon component is due to the p-process then ^{130}Xe might be effected, which would change the normalisation[11] on the heavy Xe, tending to decrease the dip at 132. Thus both the p-process and fractionation, if consistently applied, will tend to smooth the heavy Xe.

These n-process computations were done using the long time steady-state solution and thus are independent of initial composition. We conclude that a classical r-process cannot yield the observed Xe–Kr isotopic distribution. A long time n-process would fit only if there was no dip in the Xe spectrum at 132 and if the carbonaceous chondrite Kr spectrum were very different from that observed by Anders et al. It is also possible however, that the anomalous gas distributions could result from the addition of only a few or several neutrons to already existing heavy seed nuclei. (One can get a good fit if the number of free parameters equals the number of isotopic abundances to be fitted; such a procedure is not very useful.)

We are currently examining the results of adding a few neutrons to preexisting seed and limiting the free parameters by using plausible theoretical

pre-supernovae isotopic compositions and by investigating what other observable effects would result from such a neutron burst. These may well be limited to the other noble gases; effects on other elements may be masked by their much greater normal abundance. The superheavy element suggestion of Anders *et al.*[5] of course remains a possibility.

We thank D. Black and E. Anders for useful comments. This work was supported in part by NASA and the NSF.

Elevation of selenium levels in air by xerography

THE report on this subject which appeared in *Nature*[1] raises questions of methodology and relevance which I discuss here.

Although the authors calculate airborne selenium concentrations between 2×10^{-8} and 6×10^{-8} g m^{-3}, a simple calculation based on the data presented yields a concentration range 4.9×10^{-9}–14.7×10^{-9} g m^{-3}. Of more concern is the sensitivity of the analytical methods used. Their prime reference[2] reports "precision and accuracy are good for Se levels down to about 0.1 p.p.m. (1×10^{-7} g per determination) and acceptable for many purposes to 0.02 p.p.m. (2×10^{-8} g)" and reagent blanks ranging from 2 to 2.3×10^{-8} g selenium per determination. Using Olson's method[2], Harkin *et al.*[1] reported collection of from 5×10^{-9} to 15×10^{-8} g of airborne selenium in a xerography room. These values are clearly below Olson's own sensitivity limit and are even below Olson's blanks[2]. Harkin has made assurances (personal communication) that Olson's methods have been improved on and that the values reported are in excess of blanks, but the precision and

accuracy of Harkin's data cannot be verified by the methods cited.

Even assuming Harkin's results are valid, some perspective is appropriate. The highest selenium concentration reported[1] (6×10^{-8} g m^{-3}) is 3,333 times lower than the US Occupational Safety and Health Agency (OSHA) limit[3] (2×10^{-4} g m^{-3}). If one assumes a human minute volume of 8.2 l (ref. 4) and total absorption of inspired selenium[5] at the highest level reported, the total selenium ingested by inhalation in an 8-h day (2.4×10^{-7} g) would be 27 times less than that ingested by consuming a single 23-g slice of white bread (6.4×10^{-6} g)[6]. Selenium, incidentally, is considered as a nutritionally essential trace element[7].

We have measured selenium emissions from Xerox machines and have found them to be several orders of magnitude below the OSHA limit and below the usable limit of our analytical methods. Since the question has been raised, however, we have initiated a renewed effort externally to ensure that we have the most accurate data possible.

HARKIN ET AL. REPLY—Fluorimetric analysis of selenium using 2,3-diaminonaphthalene (DAN) is easily sensitive enough to determine the levels we collected from air. The sensitivity claimed[1] for the method is very conservative and can be improved by slight modifications of the basic procedure[2]. These include recrystallisation of the DAN reagent, extraction of the fluorescing Se–DAN complex with cyclohexane rather than with decahydronaphthalene, and extension of the digestion time with perchloric–nitric acid to 90 min following the first appearance of perchloric acid fumes. Sensitivities of 1 ng and <4 ng have been claimed for blank analyses by others[3,4]. Our blank values lay reproducibly at 4.7 ± 0.7 ng Se.

The question[5] of the sensitivity of the method is not really pertinent, since the figures we reported[6] were for levels above values measured in control experiments using air samples collected in laboratories in the same building as our copying room. Because the values were low for single-day air samples, to

increase the reliability of the analyses, cumulative samples taken over 4 d were actually analysed, but values were supposed to be expressed on a daily basis. Omission of the word "daily" after the values of 0.005–0.015 ng in the report[6] made them seem to be the 4-d total rather than single-day averages. The value of 20–60 ng Se per m^3 of air is the correct, rounded-off figure for the airborne Se levels.

Tolerable limits for exposure to selenium depends on the Se species concerned, and some reappraisal of current values may be warranted. The time-weighted average concentration of 0.2 mg m^{-3} permitted by the OSHA for elemental selenium and selenium oxides in air differs from the value for hydrogen selenide, which at 0.05 p.p.m. is 200 times lower than that for hydrogen cyanide, which is generally considered to be the most highly toxic common airborne inorganic compound[7]. Russian workers recently suggested that the permissible limits for SeO$_2$ should be reduced to 0.1 μg m^{-3} in air for a single exposure and to 0.05 μg m^{-3} in air for average daily exposure[8].

Comparison of inhaled and ingested selenium is of doubtful validity in the absence of toxicological work directed at this specific question. There is, in fact, evidence that selenium administered in the oxidised form can be excreted in part by respiration as volatile methylated derivatives[9].

Although excess selenium may be harmful under ordinary circumstances, its beneficial effects in counteracting heavy metal toxicity should not be overlooked[10–13]. Since there are many questions of selenium biochemistry and metabolism still unanswered, the effects of minute volatile emissions from copiers cannot be predicted with confidence. We appreciate the efforts of copier manufacturers to ensure that these emissions will be kept to a minimum and checked by independent analyses.

reviews

Delights of opisthobranch molluscs

<div style="text-align: right">V. Fretter</div>

Biology of Opisthobranch Molluscs.
Vol. 1. By T. E. Thompson. Pp. 207.
(The Ray Society, c/o British Museum
(Natural History): London, 1976.)
£15.

OPISTHOBRANCHS, the unexpected prog-
eny of shelled gastropods, have relin-
quished their protective encasement to
reveal a grace of form and colour un-
surpassed by other molluscs. Yet most
have remained relatively unknown to
the malacologist because of their re-
tiring and migratory habits and their
fondness for the immediate sublittoral,
an area difficult to explore before the
days of SCUBA diving. This is the
first book related to British opistho-
branchs for over a hundred years. It
is in two sections: the first, dealing
with the general biology of the group,
includes some magnificent colour
photographs and drawings of external
features of worldwide forms; the
second is a systematic treatment of
British species, excluding nudibranchs
(which are to be dealt with in a second
volume), the parasitic pyramidellids
and the planktonic pteropods.

No comprehensive account of the
biological activities of sea slugs has
been written previously and in the first
section the author successfully con-
veys his interests in, and personal ex-
perience of the living animals. The
text is lucid and not loaded with ex-
cessive detail so that its contents are
easily accessible to the non-specialist.
It comprises a series of chapters deal-
ing in a general way with various as-
pects of opisthobranch biology from
the point of view of functional ana-
tomy; these constitute one of the out-
standing features of the book.

These aspects are dealt with almost
on the 'type' system since each con-
sists largely of summaries of the
author's own research on a number of
species. Without wishing to detract in
any way from the value of this, I wish
that the relationship to other opistho-
branch research had been explained
more fully to provide a better under-
standing of the biology of the group
as a whole, although, as opisthobranchs
have radiated so divergently, this may
be too difficult a task. I wish, too, that
the coverage of the systems had been
complete—reluctance to enter the field

of neurophysiology, where opistho-
branchs have furnished so much im-
portant material, is easily understood,
but there are other aspects of the
nervous system than the physiological;
and there are other systems in regard
to which the views of so experienced
and distinguished a worker would have
been welcomed.

The systematic section summarises
characters of all orders, provides keys
to British species dealt with in this
volume and a description of each, in-
cluding comments on the living animal.

This will be an invaluable guide to the
taxonomist. He, like others, would be
helped by a subject index.

Illustrations of anatomy are from
the author's published works, those of
co-workers and redrawings of the
anatomy of even some of the most
accessible species from classical illus-
trations published as far back as 1845.

sity of Reading, UK.*

Meditations on a cell cycle

*Multiplication and Division in Mam-
malian Cells.* By Renato Baserga. Pp.
xii+239. (Dekker: New York and
Basel, May 1976.) SFr. 78.

PROFESSOR BASERGA'S book combines
those rare qualities of being readable,
informative and very often amusing.
The book makes no claims to be an
exhaustive study of the multiplication
of mammalian cells; ample references
direct the reader to review articles of
greater depth.

A major part of the monograph is
naturally taken up with a review of the
cell cycle and aficionados of the
relevant literature will recognise
Baserga's rather personal views on cell
cycle controls. Baserga marshalls a
number of arguments (none of them
convincing) to support the widely held
idea that G_0 cells are not merely cells
with a long G_1 which may be shor-
tened by suitable stimulae, but are a
separate class of cells awaiting their
fairy godmother to trigger them back
into the cycle. This is not just a seman-
tic argument as it determines whether
mitogenic stimulae are regarded as
triggers initiating new processes or ac-
celerators of ongoing events. I see
nothing wrong with the view that G_1
may be infinitely expandable to include
G_0. Unfortunately the cell cycle is often
drawn like the face of a clock with the
cell cycle phases apparently given defi-
nite durations. This ignores the fact
that variation in the length of cell cycle
phases (especially G_1) is the rule rather
than the exception, and failure to re-

cognise this has placed enormous
psychological constraints on the under-
standing of cell proliferation. The
criteria Baserga cites for distinguishing
between cells in G_1 and cells in G_0
result from sampling cells from widely
separate parts of a continuum of pro-
liferation rates.

The other hobby-horse Baserga rides
round the cell cycle is the idea that
new genes must be activated to trigger
cells from quiescence to rapid growth.
This may be true but I find his evi-
dence involving changes in the physical
structure of chromatin, chromatin tem-
plate activity and nuclear acidic pro-
teins far from conclusive. Recent
mRNA hybridisation studies show that
at most only 5% of the approximately
10^4 separate mRNA sequences differ
in resting and growing cells. As only
5–10% of the mammalian genome is
transcribed this difference represents
less than 0.5% of the total genome. I
find it difficult to believe that the large
scale changes in chromatin with which
he makes such a great play) are all
devoted to the derepression of such a
minute fraction of the genome.

This being said, much of the book
is good sense; anyone involved in cell
proliferation could do well to read it
if only as an antidote to the turgid
prose and thought behind much of the
burgeoning hard core of the cell pro-
liferation literature. **Robert Shields**

•Monoamine oxidase

Monoamine Oxidase and Its Inhibition.
(Ciba Foundation Symposium 39 (new
series).) (In Honour of Mary L. C.
Bernheim.) Pp. xii+415. (Elsevier/
Excerpta Medica/North Holland;
Amsterdam, Oxford and New York,
1976.) Dfl.78; $29.95.

THE present resurgence of interest in
monoamine oxidase (MAO) and its in-
hibitors (MAOIs) stems directly from
the discovery that at least two func-
tionally distinct forms of the enzyme
exist in many mammalian tissues, in-
cluding the human brain. The prob-
lem is now to assess the physiological
and pharmacological significance of
this finding particularly with regard to
the use of MAOIs in the treatment of
certain affective disorders. This volume
is intended to update and assemble
some of the more recent findings in the
field.

Almost without exception, the papers
comprising this book are of a high
standard. The first five articles deal
with the nature and properties of the
multiple enzyme forms together with
the mechanism of action of acetylenic
MAOIs. The second section catalogues
a series of re-investigations into the
physiological significance of MAO
using MAOIs that more or less speci-
fically inhibit one or other of the en-
zyme forms. A final group of seven
papers deals with the evaluation of
these newer MAOIs in the treatment of
certain types of depressive illness and
with also the possible usefulness of
changes in human blood platelet MAO
activity as indicators of such disease
states as depression, migraine and
schizophrenia.

The most interesting and revealing
portions of this volume are the 125
pages of discussion. A feeling of be-
wilderment and uncertainty is con-
stantly surfacing throughout these
pages. Is the 'amine hypothesis' of
depressive illness the correct model?
Against all preconceptions, may anti-
depressant drugs act by reducing
and not increasing the effective con-
centration of pharmacologically active
amines at the receptor site? Perhaps
the site of action of MAOIs is not in
the brain but in the periphery: the
accumulated amines may then pene-
trate the blood–brain barrier. Are
MAOIs effective antidepressants be-
cause they inhibit MAO or is it be-
cause they inhibit amine synthesis by a
feedback mechanism or perhaps block
the uptake of amines by cellular
elements in the brain? Is the ability of
the tricyclic antidepressant drugs to
inhibit one of the two forms of MAO
with a K_i of about 10^{-5} M a factor in
their mood-elevating properties? Is it
even possible to make meaningful
studies on the role of MAO *in vivo*
when that fraction associated with
nerve endings is less than 5% of the
total? These and many other problems
are discussed in this fascinating volume.

It seems absurd that so little is
known about the role of an enzyme
originally characterised as long ago as
1928 by Mary Bernheim. There is one
inescapable conclusion that may be
drawn from this book: until the aetio-
logy of depressive illness is understood
and the biochemists and clinical psy-
chiatrists achieve some standardisation
in their respective disciplines, the treat-
ment of affective disorders with MAOIs
will continue to be a 'hit-and-miss'
affair.   **Godfrey G. S. Collins**

Department of Pharmacology at the
School of Pharmacy, University of
London, UK.*

Mammalian gluconeogenesis

*Gluconeogenesis: Its Regulation in
Mammalian Species.* Edited by Richard
W. Hanson and Myron A. Mehlman.
Pp. xxvi+592. (Wiley-Interscience:
New York and London, 1976) $36.40;
£18.60.

THIS volume of 15 essays is dedicated
to Professor Henry A. Lardy for his
outstanding contributions to bio-
chemistry–impressively listed in the
introduction. The editors have sought
to compile the most significant infor-
mation gleaned from 25 years of re-
search on gluconeogenesis, an area in
which Professor Lardy has played an
important part. The chapters are group-
ed into four sections: the enzymology
of gluconeogenesis; the involvement of
the mitochondrion; the experimental
approach to gluconeogenesis in liver
and kidney; and gluconeogenesis in
man. The sections seem to cover the
main areas of current interest: the
properties and regulation of the en-
zymes unique to glucose production
that do not function in glycolysis; the
vital question of the concentration of
substrates actually available to these
enzymes; the significance of the
intracellular location of the enzymes,
particularly phosphoenolpyruvate car-
boxykinase (PEP-CK); transmitochon-
drial membrane carriage of reducing
equivalents; the interaction and com-
petition for energy and substrate
between urea synthesis and gluconeo-
genesis; the different manner of control
of gluconeogenesis in liver and kidney;
and last but by no means least what it
all means for *homo sapiens.*

As the editors point out we now know
a great deal about the pathway of glu-
coneogenesis from various substrates,
but considerably less about how the
process is controlled. It remains un-
clear whether for glucose formation
from lactate and alanine pyruvate
carboxylase or PEP-CK constitutes the
pacesetting enzyme. The activity of the
former is strongly regulated by acetyl-
CoA, but it is pointed out that we can
at present only guess at the concentra-
tions of CoA esters available to the
enzyme *in vivo*. PEP-CK exists in at
least two forms and possesses a varied
distribution between mitochondrion and
cytoplasm in different species. The level
of the cytoplasmic form in particular
responds to a number of hormones.
Although the varied distribution is
described by several authors and the
range of activities in different species
compared, there seems no suggestion of
what the rationale for this diversity
may be. The enigma of an apparent
K_m for PEP-CK towards oxaloacetate
far in excess of available concentra-
tions, resolved for the cytoplasmic
enzyme by Ballard (*Biochem. J.* **120,**
809, 1970), remains an acute problem
for the mitochondrial enzyme since the
overall mitochondrial concentration of
oxaloacetate seems so low. It was Lardy
himself who pointed out the virtue of
a cytoplasmic location of PEP-CK if
it led to oxaloacetate transfer from the
mitochondrion as malate, since this
simultaneously resulted in 2H transfer
to the cytoplasm needed at the stage
of triose phosphate formation when
gluconeogenesis is proceeding from
substrate not initially undergoing oxi-
dation. It is interesting to learn that in
pigeon liver, where phosphoenolpyru-
vate synthesis is almost entirely mito-
chondrial, negligible glucose synthesis
from either pyruvate or alanine occurs.
Except in relation to man, little con-
sideration seems to be given to the role
of glycerol as a gluconeogenic sub-
strate, yet in prolonged fasting it be-
comes quantitatively important and
could also be a source of reducing
equivalents for other precursors.

This volume will be indispensable to
all workers in the field and is to be
recommended to anyone interested in
gluconeogenesis. It is a pity that a
number of the chapters have no sum-
mary section, but, perhaps to compen-
sate, the editors have provided their
own synopsis of the contributors'
main points and the current state of
the art.   **K. L. Manchester**

*K. L. Manchester is Professor of Bio-
chemistry at the University of the
Witwatersrand, Johannesburg, South
Africa.*

obituary

Hermann Träuble was born on April 7, 1932 at Nellingen, near Ulm, and died on July 3, 1976.

It was about nine years ago that Hermann Träuble first put his head round my door with a rhetorical "Am I disturbing you?" This pleasant young man who stood there before me, with a modest and yet forceful presence, was by no means an unknown quantity to me. His teacher and supervisor at the Max-Planck-Institut in Stuttgart, Alfred Seeger, had notified me of his visit, with the words which Mozart is said to have used of Beethoven: "Keep an eye on him, one of these days he'll make the news".

Hermann Träuble had already made the news. Together with Uwe Essmann he had successfully carried out an experiment which others had only dreamed of—the direct, visible demonstration of a quantum effect. This experiment is so typical of its performer's straightforward, goal-directed methods of thought and work that I would like to outline it here in a few words. I shall try to relate the story in the way which Hermann Träuble himself described it to me.

The experiment was an attempt to demonstrate the quantisation of magnetic lines of force in a particular class of superconductors, the so-called Class II superconductors, which are characterised by a particular kind of behaviour in a strong magnetic field.

How does one make the paths of magnetic flux lines visible? The answer is known even to schoolboys: use fine iron filings—but just how fine must the filings be, to demonstrate the quantum phenomenon? One would answer intuitively: "As fine as possible, best of all a dust made up of individual atoms or small aggregates of atoms." But that would be a hasty answer, for we must recall that ferromagnetism is not a property of individual atoms, and it can only appear in ordered crystalline structures.

The question should therefore more precisely run: how small must the particles be, to respond to a quantum effect, and how large must they be to act ferromagnetically and to appear on the screen of an electron microscope.

The two young scientists grasped the bull by the horns, and simply started to experiment. Using an inert-gas atmosphere, they succeeded in producing tiny crystals with an edge length of ~ 0.000001", and then in condensing these onto the surface of a semiconductor in a magnetic field. The circulating currents in the semiconductor induced by the magnetic field are divided up into tiny vortices, which rotate about an axis parallel to the magnetic lines of flux. The minute ferromagnets deposited themselves preferentially onto this lattice of 'quanta of magnetic flux' and build up crystal nuclei, which could be seen under an electron microscope.

Result: a direct, macroscopic observation of a microscopic quantum effect!

The Physics Prize of the Göttingen Academy of Sciences awarded to these two scientists was a clear expression of the recognition with which the world of learning received this great achievement. For Hermann Träuble this was, however, not the first distinction. A short while previously he had received the Masing Preis of the German Metallurgical Society for his work on the magnetisation and hysteresis in ferromagnetic single crystals, which he had carried out as part of his doctorate.

Now he was standing in front of me. All he wanted was a post as an assistant —a man who had a brilliant career in solid-state physics in front of him and to whom a university chair was already open. All he wanted was a small laboratory, he assured me, maybe a hundred square feet—after taking a critical look at the dimensions of my study. He had taken it into his head to get into biophysics and a true Swabe can never be deflected from his intended course.

Hermann Träuble's interests in Göttingen were particularly directed at the structure and function of lipid membranes. In 1971 he published a comprehensive article in *Die Naturwissenschaften*: 'Phasenumwandlungen in Lipiden', whose subtitle 'Possible Switching Processes in Biological Membranes' already looked to the future. He hitched his own work onto that of Dennis Chapman, who had demonstrated calorimetrically the phase transitions between crystalline and liquidcrystalline states. Hermann pioneered the development of new and above all fluorimetric methods which made it possible to follow these rapid co-operative transformations. Thus he was able to investigate not only the static but also the dynamic aspects of these processes. The high speed of the phase transformations is closely connected with their potential significance as biological switching processes. Collaboration with Hansjörg Eibl made possible a comprehensive study of those membranes whose lipid constituents were already well known. Models were developed, their electrostatic interactions were studied, and the findings compared in each instance with similar or related effects in biological systems.

These were the pioneer years of a new 'membrane biophysics', full of excitement and creativity. Seldom did Hermann go home before daybreak, and even then he was always back in the Institute at five to two in the afternoon—just in time to grab something to eat in the canteen.

Wherever co-operation was offered, it was taken up. Peter Overath contributed his wide experience of the Coli membrane, and through this collaboration a detailed picture of the structure and phase transformations of bacterial membranes was put together, backed up by studies with models. Together with Erich Sackmann, who was familiar with the technique of electron spin resonance, he attacked the problem of lateral diffusion of the lipid molecules in the membrane. This turned out to be a neck-and-neck race with the group of Harden McConnell in Stanford.

He also applied his research to fundamental biological problems— a classic example of this is the paper with Hansjörg Eibl and Hideo Sawada "Respiration—a Critical Phenomenon?"; it is still too early to see the significance of his investigations for the final understanding of nerve membranes. Not without good reason was Hermann Träuble a much sought-after discussion partner in numerous workshops in the Neurosciences Research Program in Boston, USA. Listening to his lectures was a pure delight. His vital asset was that, where others had only answers, he always posed the right question.

The walls of his original laboratory had long since become too narrow. In 1974 the Max-Planck-Gesellschaft received him as a Scientific Member, and only a few weeks before his death he was appointed to a directorship in the Institute for Biophysical Chemistry in Göttingen. His research group had grown uninterruptedly in recent years, and includes today a dozen scientists, who will undoubtedly go on to extend the ideas which they and Träuble developed.

Neither was there any lack of new honours. The Faculty of Human Medicine of the University of Giessen

• awarded Hermann Träuble the Ludwig Schunk Prize in 1972 and the German Bunsen Society for Physical Chemistry the Bodenstein Prize in 1975.

The man, just 44, was called away at the zenith of his career. We shall not meet Herman Träuble again in the corridors of the Institute, or be enlivened at our tea colloquia by his burning enthusiasm and swabish charme; we shall not race together down the ski slopes in January, and I shall never have another chance of digging with him for fossils in California. Certainly, death is an integral part of life. But this insight cannot take the pain away.

Manfred Eigen

Ian Macpherson, head of the Department of Virology at the Imperial Cancer Research Fund Laboratories, London, died on September 11, 1976 at the age of 46, in the middle of a distinguished career. He was married with three children.

Macpherson was born and educated in Scotland, as a Foundation Scholar at George Herriots, and after at Edinburgh University, leading to a Carnegie Fellowship and a Ph.D. in virology in 1955. He then worked at the Microbiological Research Establishment, Porton, for four years before moving to Glasgow in 1959. After a year in the Department of Genetics, he became a founder member of the new Institute of Virology and of the Medical Research Council's Experimental Virus Research Unit. Except for a year as an Eleanor Roosevelt Cancer Fellow at the Wistar Institute, Philadelphia, he remained in Glasgow until 1968 when he was appointed to the senior staff of the Imperial Cancer Research Fund Laboratories in London to head a substantial department.

Macpherson began to study tumour viruses in Glasgow and it was for his unique and pioneering contributions to the study of virus transformed cells that he will be remembered. Of great importance was the isolation of the first line of cultured cells (BHK 21 cells) which could be used for precise quantitative evaluation of the transformation process, and which allowed direct comparison of transformed and untransformed cells from the same clonal population. Then came the discovery, with Montagnier, of the agar suspension assay system, which, with its various modifications, is of profound importance in tumour cell biology. Macpherson also isolated the first revertants of transformed cells, thus paving the way for the use by others of this important method for studying the transformed cell phenotype. In recent years Macpherson and his colleagues in London concentrated on the altered surface chemistry of transformed cells, and in particular developed the use of conditional mutants for elucidating the role of the virus.

Through Macpherson's wide reputation, his laboratory attracted visitors from far and near. He lead his group from the laboratory bench, not only by his originality and knowledge but by his experimental ability. Those associated with him soon discovered another aspect of his character as well—his impish sense of humour. This was often expressed in remarkable collages in which he delighted to ridicule any pompous and unjustified aggrandisment.

Ian Macpherson's hobby was golf, in which he also excelled, and it was on the golf course that he died.

The eminent organic chemist **George O. Curme, Jr** died on July 28 at his summer home at Oaks Bluff, Massachusetts. He was born in Mount Vernon, Iowa in 1888, the son of a professor of German who was also a renowned grammarian. Curme graduated at Northwestern University, then as a graduate student moved from Harvard to the University of Chicago, where he obtained his Ph.D. Next he went to Germany, then the Mecca of organic chemists (it has been said that in the first half of the century all organic laboratories were built pointing towards Berlin) to study under Fritz Haber and Emil Fischer at the Kaiser Wilhelm Institute and the University of Berlin.

On returning to America he worked from 1914–1920 as a research fellow at the Mellon Institute, and it was here that he started on the work which founded the synthetic aliphatic organic chemistry industry in America. (Aliphatic chemistry deals with chain-like compounds of carbon, as opposed to aromatic chemistry which deals with ring compounds.) He initially sought a method for the commercial manufacture of acetylene; he later widened his horizons to many other aliphatic compounds.

In 1917 he started to work for Union Carbide, with whom he was to remain (eventually becoming a director) until his retirement. From the Union Carbide laboratories in 1925 he announced the discovery of a process to make ethylene glycol, which soon replaced alcohol for use as an antifreeze in cars' radiators, and which rapidly developed into a multi-million dollar industry. Dr Curme continued his research, producing a new synthesis of ethyl alcohol, and later playing an important part in the wartime synthetic rubber programme.

Among the many awards he was given was the Willard Gibbs Medal, bestowed on him by the American Chemical Society in 1944 for his fundamental role in bringing "leadership in organic chemistry from Germany to the U.S.A."

October 28, 1976

Dear Mrs Williams... HELP

BRITAIN'S science funding through the research councils has got itself into a real mess these past few weeks. Shirley Williams, Secretary of State for Education and Science, whose stock is already high amongst both administrators and scientists, could well earn herself even more credit by managing to sort out a logjam which no one else has the political clout to do.

Faced like every other body with the need for economic restraint, the Advisory Board for the Research Councils (ABRC) has been saying for some time now, and most notably in its Second Report published about six months ago, that if expenditure is allowed to grow at all it is the research councils other than the Science Research Council (SRC) which will get any growth that is going. Indeed, to help fund this the SRC has had to expect to spend 2% less per year over the years to 1980. This makes the period 1973–80 one in which the spending power of the SRC in real terms is expected to fall by one-sixth.

Within that overall decline, moreover, there were to be favoured areas. Engineering research and associated schemes such as the Teaching Company, marine technology and polymer engineering, were to grow by more than 50% in the years 1976–81. Science Board research comprising biology, chemistry, mathematics and physics outside astronomy and nuclear physics is allowed a 10% growth in the same period, although all of this and more will be taken up by expansion of central facilities. On the other hand nuclear physics expenditure (at present £41 million per annum, half domestic, half at CERN) will drop to £29.5 million, with all domestic expenditure nearly halved. And expenditure in astronomy and space research will drop from £26 million to £20 million, again with the subscription to the European Space Agency assuming an increased importance. Whatever abuse may be hurled at SRC, it has certainly shown itself capable of rapid response to outside pressures for changes in direction—some of these switches mean that laboratories are having to change their rôle entirely.

Now all of this makes for a most remarkable contrast in reading between the SRC's annual report, just published (HMSO: £1.75) and the reports of the Natural Environment Research Council — NERC (HMSO; £2.65) — and the Medical Research Council — MRC (HMSO: £2.75). (Even the price difference tells the story). Whereas NERC and MRC, although generally worried by economic stringency, seem to find their biggest problems in such matters as adapting to the customer-contractor relationship and giving their researchers a stable career, SRC looks burdened down on almost all sides. But it is what has happened since the end of the reporting year (31st March, 1976) which now has everyone so much on edge. Changes in the value of the pound have put up the cost of the international subscriptions to just those agencies such as CERN and ESA that are meant to take the load off the domestic budget. Of the £6 million more that SRC needs to find, the Treasury has as yet only agreed to cover £2.5 million.

The SRC has a long way to go, and for the past three weeks has been seeing what can be trimmed, in a fashion which has put even more people on edge. Requests have gone out to directors of establishments to look at their capital expenditures with a view to making immediate savings. Major establishments will have to cut capital expenditure by a fifth in the next year and one round of new research grants, due in a month's time, is going to be deferred. The other research councils are also having to bear the load of CERN and ESA.

No one would pretend that all this unseemly grubbing around is going to bring Britain's science to a grinding halt within months. But it does seem to have generated a fair amount of unnecessary bad feeling amongst scientists. And it does pose problems about whether the whole structure of scientific research—big science and little science alike—should be so easily rocked by international exchange rates.

In the short term, it is incumbent on Mrs Williams, convinced European that she is, to go in fighting for automatic reimbursement of the increased European subscriptions. But in the longer run there is no doubt that some way must be found of giving the chairmen of research councils increased flexibility in their transactions. As it is they are committed every year down to their last penny and have no source of stand-by credit on which they could draw in situations such as these and which they could repay gradually if special pleading found no favour with the Treasury. □

● In *Nature* of September 30, page 359, the maximum permissible body burden for plutonium was given as 0.6 mg. This should, of course, have been 0.6 µg.

The Nobel prizes (1): Physics

Pioneers of the New Physics

Stuart Sharrock puts the achievement
of Richter and Ting into perspective

THE discovery of stable elementary
particles of high mass has opened up a
new era in experimental and theoretical
particle physics. For their pioneering
work in this discovery Professor Burton
Richter of the Stanford Linear
Accelerator Center (SLAC) and Profes-
sor Samuel Ting of the Massachusetts
Institute of Technology have been
jointly awarded the 1976 Nobel Prize
for physics.

The existence of a new particle was
announced simultaneously by the two
experimental teams in November 1974.
It was observed independently by
Ting's group working on the proton
accelerator at the Brookhaven National
Laboratory (BNL), and by Richter's
team at the electron–positron storage
ring facility at SLAC. The new
particle, called J at BNL and ψ at
SLAC, is a neutral meson of high
mass, 3.1 GeV, and with the amazingly
narrow width of 100 keV. It is difficult
to detect with proton machines, and its
discovery at BNL was a great feat of
experimentation. In contrast it is
copiously produced in electron–positron
annihilation, although its narrow width
makes it elusive. Within a few days
of the announcement of the J/ψ the
SLAC team had discovered a further
state, the ψ' at 3.7 GeV.

The existence of stable particles of
high mass was unexpected. The J/ψ
is a spin 1 particle and is more than
twenty times heavier than the lightest
such particle, the pion. The J/ψ should
rapidly decay into lighter known par-
ticles, yet its lifetime (related to its
width through the uncertainty prin-
ciple) is about 1,000 times longer than
expected. Furthermore the J/ψ does not
fit into the well-established three-quark
classification scheme. A new law of
nature is therefore necessary to explain
its decay properties and extremely long
lifetime.

Of the four known forces between
particles only the electromagnetic inter-
action is understood. Both Richter and
Ting have in the past contributed to
this understanding by demonstrating
the validity of the theory down to
distances of the order of 10^{-14} cm.
Attempts at a unified field theory for
the weak and electromagnetic inter-
actions based on the principle of 'gauge
invariance', in which an additional
symmetry is assumed to exist between
the two interactions, have had some
success in recent years, particularly
with the prediction and subsequent

observation of the neutral current weak
interactions. The theories require the
existence of a fourth quark, dis-
tinguished by the name 'charm'. This
new quantum number has successfully
explained the J/ψ particle as a bound
state of a charmed quark and a
charmed anti-quark.

If the charmed quark is heavy then
the long lifetime of the J/ψ is ex-
plained. The bound state of charm-
anticharm is similar to that of the e^+e^-
system in positronium, and is called
charmonium. A number of energy
levels are expected in this model and
many states have now been found fit-
ting well into the predicted level
scheme. The investigation of charmo-
nium promises to play a key role in
the understanding of strong inter-
actions by providing information on
the force acting between quarks.

Particles are classified as hadrons
if they have strong interactions and
leptons if they do not. The addition of
a charmed quark to the three conven-
tional quarks provides a set of building
blocks from which all known hadrons
can be constructed. It also provides a
symmetry between leptons and quarks,
and there are now four of each with
interactions that can be expressed in
terms of the same set of mathematical
rules. The detection of the new par-
ticles has given rise to a new branch of
hadron physics which could lead to a
better understanding of the symmetries
governing the structure of elementary
particles. Just as the discovery of
neutral currents may help to unify the
weak and electromagnetic interactions,
the concept of a charmed quark could
well indicate links between the weak
and strong interactions.

Professor Ting's experiment at BNL
was part of a systematic and precise
study of lepton pairs produced in
hadron–hadron collisions. This study
was started in 1972 and, to cover the
mass region 1–50 GeV, involved experi-
ments at BNL, the ISR in Geneva and
the electron synchrotron DESY in
Hamburg. One of the aims was to
search for long-lived particles decaying
into lepton pairs. These experiments
are very difficult as the rate of electro-
magnetic pair production in hadron–
hadron collisions is extremely low
compared to the rate of production of
hadron pairs. The experiment had to
reject hadron pairs by a factor of at
least 100 million. During the period
August–October 1974 the Ting group

Burton Richter

Samuel Ting

had seen a narrow peak in the effective
mass distribution of electron pairs, and
had performed many detailed checks to
prove that the peak was a real particle.
The announcement of the discovery
was withheld at first while the experi-
ment was modified to search for pos-
sible further new phenomena. The in-
evitable rumours began to circulate
and the group decided to publish at the
beginning of November. Around this
time the new particle was also seen at
SLAC and the results of the two
experiments were published simultan-
eously.

At SLAC, Richter's team had been
working with the immense magnetic
detector at the electron–positron stor-
age ring complex (SPEAR). They had
compiled a large volume of data on the
total cross-section for e^+e^- annihilation
as a function of energy. On checking
through these data an anomaly was
observed at one particular energy set-
ting: inconsistent values of the total
cross-section were obtained in measure-
ments taken at the same nominal
energy. The group decided this
anomaly had to be cleared up, and at
the beginning of November they
decided to investigate the energy
region in detail. Within hours of start-
ing an extremely narrow peak in the

cross-section had been seen. This effect was so strong and clear that the group immediately sat down and wrote the draft of their paper announcing the discovery of the new particle. The following day Richter and Ting met at a committee meeting and to their mutual astonishment started to tell each other about the interesting physics results they had found.

Burton Richter was born in 1931 in New York. He decided to become a scientist as a child in high school, a physicist as an undergraduate, and a particle physicist after obtaining his PhD from MIT in 1956. Richter, always fascinated by electrons, sought a job at SLAC where he performed experiments demonstrating the range of validity of quantum electrodynamics

down to very small distances. He has long been a proponent of the virtues of electron–electron scattering and was instrumental in the commissioning of the e^-e^- colliding beam machine at SLAC. During this time he designed an e^+e^- storage ring and worked for ten years to create the complex known as SPEAR. His team working on SPEAR began experiments in 1973 culminating in the discovery of the ψ family of particles and the subsequent measurement of their properties.

Samuel Ting was born in 1936 in Michigan but returned to China with his parents when he was two months old. At the age of 20 he returned to America with $100, very little knowledge of English and a determination to go to university. Within a short time

he had obtained a degree and a PhD from the University of Michigan and decided to become an experimental physicist. After a year at CERN he returned to teach at Columbia University in 1965. At Columbia he proposed an experiment at DESY to check a recent experimental result which appeared to show a violation of quantum electrodynamics. This was accepted, and in 1966 he began a long association with DESY in which he performed experiments extending the range of validity of quantum electrodynamics and determining the properties of vector mesons. His work over the last decade on lepton production culminated in the discovery of the J/ψ by its decay into electron pairs. □

The Nobel prizes (2): Chemistry

Boranes surgery

A **Special Correspondent** looks
at the work of William Lipscomb

IT is no surprise to chemists that Bill Lipscomb should have been awarded the Nobel Prize for his beautiful work on the boron hydrides. The layman may, however, be baffled, wondering what these oddly-named entities might be, and why they should have merited years of study by a leading crystallographer who is no less well known for his more recent work on the structure of enzymes.

The story goes back more than half a century, to the time when the great inorganic chemist Alfred Stock reported that the simplest compound of boron and hydrogen is not BH_3, as one would expect by analogy with BF_3, but its dimer B_2H_6. The trouble with B_2H_6, and with all the other boron hydrides which he described, was its "electron deficiency". If the molecule had an ethane-like geometry (as the evidence of electron diffraction was held to indicate) it would need 7 electron-pair bonds to hold its atoms together, but only 12 valency electrons were available for the purpose. This ominous crack in orthodox valency theory was papered over by Linus Pauling, who advanced special reasons why the B–H bond should be able to make do with less than 2 electrons, and proposed structures for the higher boron hydrides in line with this idea.

In 1943 Longuet-Higgins and Bell showed that the chemical and spectroscopic evidence on B_2H_6 harmonised less well with an ethane-like structure than with a bridge structure, in which

two of the H atoms are situated in the middle of the molecule. It appeared that B_2H_6 manages to hold together, not by starving all its bonds of electrons but by sharing two electron pairs between the two sides of the central bridge. The bridge structure was confirmed soon afterwards by W. C. Price, and in 1949 it was proposed that one should regard B_2H_6 as containing two "liaisons triatomiques", or "3-centre bonds", neatly describable in terms of localised molecular orbitals. But the higher boron hydrides remained a puzzle.

At this point the crystallographers grasped the initiative, and Kasper, Lucht and Harker led off with a definitive determination of the molecular structure of crystalline $B_{10}H_{14}$. Their results if anything deepened the mystery: the bonding in this molecule clearly involved principles more general than those which had been advanced for B_2H_6, and it became clear that a full understanding of these principles must await the collection of structural evidence on the other boron hydrides.

It was Lipscomb who took up this challenge. Undaunted by the pathological instability of most boron hydrides and the acute difficulty of "seeing" hydrogen atoms by X-ray diffraction, he and his colleagues completed a sequence of brilliant experimental studies of the hydrides described by Stock, and of others isolated in his own laboratory. A pattern soon

William Lipscomb

began to emerge which could be interpreted in terms of "3-centre bonds" of various novel kinds, together with "many-centre bonds", for whose possible existence there were solid grounds in molecular orbital theory. Simultaneous theoretical studies in England and by Lipscomb's group predicted the existence of a stable ion $B_{12}H_{12}{}^{--}$ with icosahedral symmetry. .

The preparation of the potassium salt, and the subsequent determination of its structure by Wunderlich and Lipscomb in 1960, set the final seal on the molecular orbital theory of the bonding in these remarkable substances. The fascinating work of Lipscomb and his colleagues is a story of the fruitful interplay between imaginative theory and skilled experiment, leading to a genuine "breakthrough" in our understanding of the forces which bind atoms together. No longer is there a dichotomy between the chemist's "covalent" bond and the "metallic" bond of the physicist: Lipscomb's work showed us that at least one element succeeds, in its hydrites, in forming both kinds of bond within the same molecular species. □

The Nobel prizes (3): Medicine

Antipodean . . .

Carleton Gajdusek's attainments
stretch beyond virology. **Cedric Mims**
outlines his work and assesses its significance.

C ARLETON Gajdusek came into medical virology in the early 1950s and he soon developed a particular interest in the haemorrhagic fevers of the USSR and the Far East. His work on virus infections took him to many other parts of the world including South America, the Middle East and a number of Pacific Islands. Not content merely to investigate the viruses infecting a given population he also made extensive studies of the behaviour, development and language of the people. In all but name he became an anthropologist. During the 1960s he could be counted on to talk with authority not only about the exotic diseases occurring in peoples in remote corners of the earth, but also about aspects of their physical and cultural anthropology. In 1959, at the National Institute of Health in Bethesda, Maryland, he became simultaneously director of a programme for studying child growth and development in primitive cultures and director of the laboratories for slow, latent and temperate virus infections.

It was in 1957, during an expedition to the highlands of New Guinea, that he encountered the disease kuru, and together with Vincent Zigas, the local physician who already knew the disease, he brought kuru to the attention of the rest of the world. Kuru was a chronic neurological condition, progressive and fatal, affecting especially the cerebellum and occurring in a sharply localised area inhabited by the Fore tribe. In these people it was responsible for more than half the total deaths after infancy, and in some villages at least half the women were affected.

Initial thoughts about the role of local genes, local plant or other toxins, were dramatically swept away after Dr Hadlow, of the Rocky Mountain Laboratory, Montana, had pointed out that the brains of patients with kuru bore a histological resemblance to the brains of animals suffering from scrapie. Scrapie, another chronic degenerative neurological condition affecting sheep, was known to be transmissible experimentally from animal to animal, but only after an unusually long incubation period of a year or two. Gajdusek therefore flew refrigerated brains from patients with kuru to the Washington laboratory where in August 1963 his close col-

laborator, Joe Gibbs, injected the brain suspensions into two chimpanzees. Twenty-one and thirty months later the injected animals were seen to sicken with a disease closely similar to kuru and their brains showed almost identical pathological changes.

The disease could be transmitted from chimpanzee to chimpanzee, in whom the average incubation period was 22 months, and in subsequent experiments various other primates were found to be susceptible. All the usual laboratory tests for microorganisms were negative, except for a number of chimpanzee viruses which were recovered and appeared to represent the normal viral flora of the brain. The transmissibility of the agent from animal to animal and its assay ($10^{7.5}$ infectious doses present per gram of brain) firmly established that kuru was caused by an infectious agent. But kuru, being closely similar in its properties to scrapie, was not a conventional virus and to this day its composition and mechanism of replication is unknown. For the first time therefore, a chronic neurological condition of man, in which there were no pathological or other signs of infection, had been shown to be due to a transmissible agent.

'It seems probable that we have still not gathered the full harvest of the discoveries made by Gadjusek'

Throughout this work and during his frequent visits to New Guinea, Gajdusek had both the opportunity and the energy to exercise his anthropological interests. As a result of this he wrote various monographs, produced films and contributed to paediatric journals. The marriage of virology and anthropology bore appropriate fruit when it became clear that the disease kuru in New Guinea was transmitted from person to person by cannibalism. The disappearance of cannibalism in this part of New Guinea has meant that kuru too has now almost disappeared.

Kuru is restricted to a small zone

in the highlands of New Guinea, where a total of some 2,000 cases has been reported since its discovery in 1957. But the discoveries about kuru have sparked off a fresh approach to other chronic degenerative neurological conditions of man which are of unknown aetiology, such as amyotrophic lateral sclerosis and parkinsonian dementia. So far one of these conditions, called Creutzfeld Jacob disease, has been shown in Gajdusek's laboratory to be transmissible to primates and caused by a replicating infectious agent similar to kuru. Creutzfeld Jacob disease is rare, but the infectious agent has now been recovered from the brains of patients in five continents of the world. It seems quite likely that the neurological disease is the tip of the iceberg and reflects widespread sub-clinical infection.

At about the same time as the discovery of kuru, certain conventional viruses had been shown by others to be responsible for obscure and chronic neurological conditions. Measles virus was recognised as a cause of the rare disease subacute sclerosing panencephalitis, and JC virus, a new human papovavirus, came to be associated with progressive multifocal leucoencephalopathy. Once again the infectious agent was seen to persist in the body and cause a disease after a period of several years.

It is against this background that Gajdusek's work on kuru must be assessed. It is now firmly established that chronic diseases of man, especially neurological diseases, can arise as a result of the slow but relentless multiplication of certain infectious agents, sometimes referred to as "slow viruses", which cause disease many years after initial infection. The possible incubation period with kuru, for instance, is between 10 and 15 years. Much of the recent excitement in multiple sclerosis research arises from observations based

Carleton Gajdusek

on this concept. It represents a great step forward in our understanding of disease and it seems probable that we have still not gathered the full harvest of the discoveries made by Gajdusek. These discoveries, moreover, may well prove to be of more than mere biological interest, because traditionally microbiology has moved from the recognition of an infectious aetiology to the development of a vaccine and thus to the prevention of the disease.

The agents responsible for kuru, Creutzfeld Jacob disease and scrapie pose major problems for the investigator. All assays and tests depend on the lengthy incubation period in experimental animals and it may take more than a year to learn the result of a single experiment. Other microbiologists would have shied away but Gajdusek's insight, patience and persistence have ensured that the infectious origin of kuru was discovered and the

disease given an important place in our understanding. He has been the pioneer and the central authority in this area of biomedical research. His encyclopaedic memory, his familiarity with strange places and primitive peoples have generated many legends. He is the sort of man one might have expected to win a Nobel prize and at the same time it is both a surprise and a pleasure to find such a gentle and likeable man behind the legends. □

... encounters

A **Special Correspondent** describes
the discovery made by Baruch Blumberg,
'one of the success stories of the century'

SURPRISE, suspense and success are the three indispensable ingredients cin a good detective story, and none of them is absent from the events which led up to the discovery and evaluation of Australia antigen, now usually known as hepatitis B antigen, or HB antigen.

The story starts nearly 20 years ago, when Dr Baruch Blumberg, one of the recipients of the 1976 Nobel Prize for Medicine, was at work on proteins in the blood. It is well known that humans show individual variation in the antigens, or blood group substances, on their red blood cells. Blumberg set out to detect and compare comparable substances in the plasma as opposed to those on the cells. Using as antisera specimens from patients who had received many transfusions, a reacting antigen was found in an Australian aborigine.

The surprises began when this was found to be widely, if unevenly, distributed in human blood throughout the world. The United States, where Dr Blumberg was working, was in fact relatively free from it, although a survey of patients revealed that cases of leukaemia, Down's syndrome (mongolism) and hepatitis figured among those who were positive. The question began to be asked: was this in fact not a simple protein antigen but a human leukaemia virus?

The possibility of being able to detect and study such a virus opened wide horizons—but it was now that the suspense began, because it quickly became unlikely that it was, in fact, a leukaemia virus. A common factor in leukaemia and Down's syndrome is altered cellular immunity; in addition, patients with leukaemia have many transfusions with a concomitant oppor-

tunity for acquiring hepatitis, and children with Down's syndrome (at least, those of them in institutions) are notoriously prone to hepatitis.

It was about this time that hepatitis B infection, acquired from transfused blood, broke upon the haemodialysis trade. The transmission of hepatitis B virus, undetectable by any means except the production of the disease in a patient, had always been a problem in blood transfusion and the use of blood products, but the disasters which overtook staff and patients in dialysis units had made it doubly urgent to find a means of recognition, a serological marker for the presence of the agent.

It is now well known how, during the late 1960s, it became clear that Australia antigen was such a marker—but was it, in fact, the hepatitis B virus? When examined by negative staining it did, so to speak, come to life, and at least some of the particles could be seen to be acceptable as virus. By now it has been possible to purify these particles, and to determine that they have double-stranded DNA and a DNA polymerase, and in fact to do many things with them except grow them in a laboratory system.

Many medical microbiologists must have hoped that this would give a clue to growing hepatitis B virus in a cell culture system, but so far they have been disappointed. However, this has not prevented the use of HB antigen to study the natural history of hepatitis B virus, to detect carriers, and, to detect antibodies in human serum, and this is where the third ingredient, a successful conclusion, comes in.

As a corollary, it is possible to prevent many cases of hepatitis B (post-transfusion and otherwise) and hence to make haemodialysis, blood transfusion,

Baruch Blumberg

and the use of blood products infinitely safer. Unfortunately, there is still no conventional small laboratory animal, but the chimpanzee serves as a possible, if expensive, source and host. Even a vaccine has been prepared from HB-antigen-positive human blood, and even though its worth has yet to be assessed, there is little doubt about the effectiveness of the passive immunity conferred by the injection of concentrated, purified, specific anti-HB immunoglobulin.

Although the final evaluation of HB antigen involved, in the end, many laboratories, the work all springs from the researches of one principal and primary investigator. Even if, by hindsight, the connection between the molecular genetics of polymorphism and the prevention of hepatitis B in haemodialysis units all over the world seems to involve a series of knight's moves in chess, the consequences of Blumberg's discovery, judged as a piece of preventive medicine, must rank as one of the success stories of the century. Perhaps in this respect it is as near as any previous award to Alfred Nobel's desire to reward those whose discoveries have been of benefit to mankind. □

Now New York steps in

The New York State Attorney General's office is considering whether or not to impose controls on recombinant DNA experiments performed in facilities in the State. Colin Norman reports from New York

A windowless hearing room on the 47th floor of New York City's World Trade Center last week provided a somewhat unlikely venue for another round of public hearings on the potential risks and benefits associated with recent advances in genetic engineering. The hearing marks a potentially important development in the long process of regulating recombinant DNA research in the United States, for it is the first time that the matter has been taken up by a state government.

Called by the New York State Attorney General, Louis J. Lefkowitz, the hearing was designed to elicit the views of various concerned individuals —mostly scientists who have been in the thick of the debate over the potential hazards of recombinant DNA research for the past two years—on whether New York should impose its own controls on the research and, if so, just how strict those controls should be.

The crux of the discussion was concerned with two closely related issues. First, whether the guidelines, published by the National Institutes of Health last June to control recombinant DNA experiments which NIH supports, are strict enough to guard against possible public health hazards. And second, whether or not the guidelines should be enforced in New York State by law.

The outcome of the discussions in New York will be closely watched elsewhere in the United States, for other states are likely to take up the matter at some stage. Already, the City Council of Cambridge, Massachusetts, has imposed a temporary moratorium on a few types of recombinant DNA experiments at Harvard and Massachusetts Institute of Technology, while a special review board, consisting of city residents, is looking into the risks and benefits associated with the research. (The Cambridge moratorium was due to expire on October 7, but it has quietly been extended until January 7 to allow the board more time to make its recommendations.) And a committee of the City Council in San Diego has also

been taking evidence from both supporters and opponents of the research. New York is the first state to consider adopting legal controls, however.

According to one official in the Attorney General's office, a major factor which led New York to look into the matter is the fact that the NIH guidelines apply only to NIH grantees, and there are no legal sanctions which can be applied if the guidelines are violated. Research supported by industry, and even by other government agencies, is not formally covered. Thus a prime consideration in New York is whether or not the controls should be backed by the force of law and made to apply to all facilities, including industrial laboratories.

Last week's hearings consisted of a parade of about a score of witnesses who urged the State government to undertake a variety of measures ranging from doing nothing to banning virtually all recombinant DNA experiments in the state. The hearings were mostly low-key, punctuated by some fairly gentle questioning by officials in the Attorney General's office. They contrasted rather starkly with the highly charged, emotional nature of the Cambridge City Council's hearings earlier this year.

Leading the call for a moratorium on the research were George Wald of Harvard, Leibe Cavalieri of the Sloan-Kettering Institute. Erwin Chargaff of Columbia University and Jonathan King of Massachusetts Institute of Technology. Cavalieri kicked off with a critique of the guidelines and the way in which they had been developed, arguing that there had been only "token" input from the public, and suggesting that "it is up to society to see that the research effort is directed toward solution of problems, not the creation of new problems". Cavalieri was the only speaker to dwell at length on what he called "the hazards of success", suggesting that so far the discussion of recombinant DNA research has failed to consider the implications of the successful manipulation of the genetics of, for example, crop plants. The result, he said, "would be a change in the intricate balance of our environment, which has taken millions of years to establish".

Wald was the most outspoken critic of the research and the guidelines, however. He suggested that the recent outbreak of Legionnaires

Disease in Philadelphia has provided "a beautiful model" of what a public health problem with recombinant DNA research would be like— "unidentifiable and impossible to trace to its source". Wald argued that recombinant DNA research should not be conducted in universities, but it should be isolated in one or two national safety facilities.

As for proponents of the research, the most outspoken was James Watson, Director of the Cold Spring Harbor Laboratory. Watson said that he once told former Presidential candidate Sargent Shriver that the furore over recombinant DNA research is "the most overblown thing to enter the American scene since (President Kennedy) created the fallout shelter". Watson argued he could see no danger in transplanting genes from higher organisms into viruses or bacteria, and he said that he could see little hazard even in transferring genes from viruses known to cause cancer in animals into bacteria. The impact of infection by such organisms would be "negligible" compared with the impact of infection by the viruses themselves, he said, and suggested that "the marginal danger of this thing is a joke compared with other dangers". He suggested that the Attorney General's office could better spend its time looking into the potential health hazards of hair dyes and flame retardants in children's clothing. "What started as an attempt by the scientific community to be responsible takes on the aspects increasingly of a black comedy", Watson stated.

Faced with such widely conflicting viewpoints, the New York Attorney General's office is going to have a tough time deciding whether or not to impose additional controls on researchers in New York. Its decision will, however, be carefully watched in other state capitals. □

● **Eleanor Lawrence adds from London:** The US National Institutes of Health guidelines and the report of the British Williams Committee have now been followed by recommendations for the conduct of *in vitro* recombinant DNA research by two European organisations, the European Science Foundation (ESF) and the European Molecular Biology Organisation (EMBO).

The ESF makes a number of suggestions. It says national registries of recombinant DNA research, analogous to the Genetic Manipulation Advisory Group proposed for Britain, should be set up in each country. It also suggests that all industrial, university and government laboratories be legally obliged to declare relevant aspects of

their work to such a registry. The supervisory and monitoring machinery would remain a national responsibility. There is a further recommendation that the code of practice drawn up by the Williams committee be followed rather than the NIH code since Williams specifies a greater degree of physical containment for most experiments, and is more flexible.

The EMBO guidelines also support the idea of national advisory groups, which would specify the conditions of containment to be used. EMBO says that either the Williams or the NIH codes of practice may be followed, but not a mixture of both. The different degrees of emphasis on biological and physical containment in the two codes, it contends, could lead to confusion.

Both organisations emphasise the need for regulations to operate at the same level in different countries and

therefore suggest that the national advisory committees should meet regularly. In addition they both propose that suitable experiments should be undertaken to assess the conjectural risks associated with recombinant DNAs and to pave the way towards eventual adjustments to the guidelines.

In Britain, however, many biologists are unhappy about the draft Health and Safety Commission (HSC) regulations now being circulated for comment. The regulations require among other things compulsory notification to the HSC of any experiment intended "to alter or likely to alter the constitution of any microorganism". Although the HSC has asked which experiments should be excluded, this type of blanket regulation, and the fear that proposals submitted to the HSC would be delayed interminably by bureaucratic machinery, have stimulated a group of

scientists to ask government that the HSC regulations should be withdrawn completely. They wish to see the voluntary procedures recommended by Williams followed instead.

There is strong feeling that in this instance the HSC is not the most appropriate body to deal with the complex scientific issues involved and that public interest would be better served if they were considered by an expert committee such as the Genetic Advisory Manipulation Group for example. The Health and Safety Commission would still have powers under the present Health and Safety at Work Act to inspect laboratories to see whether the containment procedures recommended by Williams were being implemented, and could probably be brought in by GMAG to prevent experiments considered unsafe being carried out. □

COMECON

● Scientific cooperation between Comecon countries is still "incommensurable" with the requirements and potentialities of the member countries, according to the Polish journal *Sprawy Miedzynarodowe*. The relatively slow development of joint research and development projects is to a certain degree attributed to "subjective factors" such as lack of personal initiative, but also to the "excessive autarchic tendencies" of individual bodies which often necessitate intervention by the "central authorities" (that is, Party and Government) of the member countries.

A number of remedies are proposed to help the integration of research which is a fundamental tenet of Comecon planning. Most of these relate to improvements in organisation and management, the integration of science and industry and so on. One, however, suggests a basic lack in the whole policy of cooperation. This involves the question of funding. At present, it appears, the necessary funds are obtained often only after protracted negotiations between the countries concerned. To speed up the process, it is suggested that a special fund should be created within the International Bank (in Moscow) for the integration of research and development in the Comecon countries, with, in due course, the possible establishment of a Comecon bank especially for the financing of research.

● Since the discovery of lasers, laser research has been seen as a modern and progressive subject, eminently suitable for Socialist countries. The Second International Conference on

Luminescence at Szeged in Hungary last month showed that interest continues unabated. In particular, a Hungarian team described the use of lasers to determine "hitherto-undiscovered properties of substances", while Soviet, Polish and East German specialists reported considerable success in the use of lasers to investigate photosynthesis.

● Cosmonauts from all the Comecon countries—including Cuba and Mongolia—are to take part in manned space-flights between 1978 and 1983 as part of the Interkosmos programme. Until now, the programme has consisted solely of the launching of unmanned satellites, put into orbit by Soviet rockets and carrying experiments and equipment provided mainly by the Soviet Union with some participation from the European members of Comecon, notably East Germany and Czechoslovakia. Not surprisingly, Soviet participation in the new programme will also be considerable: as well as providing the spacecraft, orbiting stations, and launch facilities,

the Soviet Union will train the cosmonauts—training will take place at the Soviet "Yuri Gagarin" training centre. And the wording of a recent TASS communique suggests that at least one crew member in each flight will be from the Soviet Union.

●*Chemicisation*, the massive, widespread, undesirable use of artificial fertilisers, has long been a cornerstone of Soviet agricultural policy, and, not surprisingly, has become standard practice in other Comecon countries. In certain cases, however, the results have not been entirely successful. In Hungary, for example, excessive use of fertilisers has considerably reduced the sugar content of sugar beet in recent years, so that while the yield of beet itself has increased steadily, the overall sugar yield has remained constant. To encourage the production of maximum-yield crops rather than overall gross bulk, the Director-General of the Hungarian Sugar industry recently announced a new scheme of payment for sugar-beet crops under which farmers will receive a premium based on sugar content. The Hungarian experience is, apparently, not unique: recent Soviet resolutions on the further improvement of agriculture stress the need "to increase research on the study of the effect of mineral fertilisers and other chemical products on the quality and biological total value of agricultural production". This marks a radical change from traditional attitudes: until now the largest crops rather than the best have always won official acclaim.

Vera Rich

Same song, different meaning

Chris Sherwell reports on the latest developments on the European Community's research front

THE EEC's Council of Research Ministers did their turn again at the end of last week when they met in Luxembourg. In most respects it was a repeat performance of a long-running drama, but it did have the added merit of a new act to take it further towards the worthy ending it has so far lacked.

The Ministers were unable to make the crucial and much-delayed decision on the siting of the Joint European Torus (JET), the Community's sorely afflicted fusion project. It was that which made the meeting a repeat performance. But earlier expectations of progress on this particular matter had begun to die anyway, principally because the whole issue has in recent months become inextricably intertwined with the Community's four-year joint research programme, now under discussion.

When the Ministers left Luxembourg they had at least resolved a good deal concerning JET apart from the site. They were able to agree certain details regarding financial arrangements (though not others), as well as the project's legal status. It was these accords which helped mainly to redeem the show, but until the site is decided they can have little real practical meaning.

The meeting agreed that the European Commission will put up 80% of the costs, with the host country bearing 10% and the other participating countries the remaining 10%. The host country will also meet the costs associated with supplying the site with basics and with dismantling the project on completion in several years' time. At that point the equipment will be the host country's property. The Ministers further agreed that the project was a "joint enterprise", that is, independent of the host country and a Community project to be identified as such.

They were, however, unable to decide on staff numbers, although there was agreement that the host country would second people to the project and that others would be engaged as temporary agents of the Commission. Outstanding matters will be discussed by the member states' permanent representatives in Brussels, as will another issue, the precise costs involved. Since the Commission contribution of 108 million units of account (at March 1975 prices) was agreed, costs have risen and the project is being talked of in terms

of a four-year construction effort rather than five years. Some modification may therefore be necessary.

Much of this was largely in line with Commission proposals made a couple of weeks earlier. Regarding the site, however, the Commission was in favour of the Joint Research Centre (JRC) at Ispra in Italy—itself nothing new—but had made a new proposal should no Council decision be reached before the end of the year. In that event, it suggested, the matter should be passed over to the Commission itself, which would then decide on the basis of an opinion from its own JET committee— which decided matters by a two-thirds majority.

This, a precedent which did not look like attracting many Ministers, was not discussed in Luxembourg. Another complication had already crept in some weeks earlier, when it was agreed to discuss JET in the context of the four-year joint research programme. Although designed to hasten agreement on the JET site, it introduced a bargaining element well suited to Community *realpolitik*. With details of the research programme themselves matter of dispute, movement on JET became contingent upon movement on the research programme.

At last week's meeting demands concerning the programme came, perhaps ironically, from three of the four main contenders for JET— Britain, France and Germany. Britain's starting position, on which it is flexible, was to seek reductions in staff of about 20% and cuts in certain expenditures amounting to £15 million at the Community's four research centres. Italy argued that this would threaten the centres, especially Ispra, the fourth JET contender. No one is saying that Italy and the Commission are now preparing for the worst, but there is speculation that if JET isn't to go to Ispra only a large alternative research programme—perhaps the one proposed, intact—would provide sufficient compensation.

Certainly the British were keen to emphasise that the site decision ought to be taken on scientific and technical grounds only. That would help the Culham site's case, but there would still be the matter of the French and German sites of Cadarache and Garching. Of the two, Germany with its stronger economy is the stronger candidate, yet the opportunity to strengthen its case still furhter through a higher host country contribution was apparently allowed to pass. French

research faces similar problems to Britain's, but this may say more about the relative weakness of its candidacy than Britain's ability to take on the project. The latter's enthusiasm for the project going to Culham remains undiluted by the current crisis facing its research community and economy generally.

As the Luxembourg meeting broke up the recipe was there for a good deal of haggling between the parties between now and the next Research Ministers' meeting on November 18. The understandings reached on JET and the joint research programme are provisional until a decision on the JET site is reached. If that decision, already delayed a year, is not made then, it could pass directly to the Council of Prime Ministers. If they didn't agree and refused to leave the matter to others, the Commission could go on funding the project in the way it has done hitherto. The fate of the project, however, will be more uncertain than ever. □

● The European Science Foundation (ESF), members of which are national research councils and academies in Europe, is due to hold its general assembly in Strasbourg this week. The Foundation involves a total of 43 member organisations from sixteen European countries. The President of the Executive Council, which will present its second report to the assembly, is Sir Brian Flowers, the UK physicist.

The Foundation aims to encourage the emergence of a close-knit community of science and research in Europe; this is also a goal of the EEC proper, with which the ESF has links through the Director General for Research, Science and Education at the European Commission. The ESF endeavours to do this by providing a forum for the exchange of information and experience, particularly regarding the way the member organisations actually operate. It also seeks by this method to encourage activity aimed at producing joint European action in certain fields.

As an international non-governmental non-profit organisation it lacks the financial means to give effect to its advice, but it can and does examine specific areas and maintains contacts with other concerned organisations, like EMBO and ESA. The Executive Council reports further progress in such areas as astronomy, space science, genetic manipulation and mathematics, in all of which it had sought to take initiatives during its first year of existence.

IN BRIEF

SERI delay

Another three-month delay has been announced by the Energy Research and Development Administration (ERDA) in the timetable for establishing the Solar Energy Research Institute (SERI), the facility which may eventually become the focal point for solar energy research in the United States. ERDA was hoping to choose a contractor to operate SERI and a site for the facility in December, but it now says that a decision cannot be made before March.

The delay stems chiefly from the fact that there is fierce competition among states for the contract to operate SERI, which will bring considerable amounts of federal money, jobs and prestige. ERDA has received 20 proposals for the contract and so far has eliminated only one of them.

The three-month delay is only the latest in a series of setbacks to the plans for SERI, first approved by Congress in November 1974.

SGHWR report shortly

Last week the final witnesses gave evidence on Britain's choice of nuclear reactor to the House of Commons Select Committee on Science and Technology. The committee says it hopes to publish its report in about a month, having questioned the Energy Minister Mr Benn, the Central Electricity Generating Board and the South of Scotland Electricity Board, the UK Atomic Energy Authority and the National Nuclear Corporation, and the Health and Safety Executive and Electrical Power Engineers Association.

Since the choice of the British Steam-Generating Heavy Water Reactor two years ago it has undergone substantial modification (a reference design was only submitted in June of this year) and expenditure on it was deferred for a year in this summer's government spending cuts. Continuing doubts about whether it was the best choice made the committee decide to look at the whole question afresh.

Protest over Nacekuke closure

Civil service unions are protesting to the Secretary of State for Defence about the plans to close the Chemical Defence Processing Establishment at Nancekuke, Cornwall—due, according to the unions, in March 1978. Some of the work of the station will be moved to Porton Down in Wiltshire, another defence establishment.

The union objects on the grounds that Nancekuke's function is the production of defence chemicals, a job that Porton Down, a primarily research establishment, is not equipped to do. According to the 1973 Nugent report, closing the station would save around £80,000 a year, mainly in administrative costs, but the unions claim that money would not be saved.

LEGISLATION to control toxic chemicals was as inescapable as are the facts that all substances are chemicals, all chemicals (depending on the level) are toxic, and all human activities are the target of regulation. Passage of the new law was accelerated by some notable gaffes by industry. Some of these mistakes were inadvertent because they preceded recent advances in toxicological testing. In other cases there was a reluctance to adopt known procedures in testing industrial compounds; some of these had long been obligatory for proposed new agricultural chemicals and food additives.

Insecticides bore the brunt of the earlier demands for increased regulation, perhaps because the methods used in applying insecticides were often easily visible, as when residential areas were sprayed to control mosquitoes. Conversely, food additives got into trouble with the public partly by being honest. Their names are required on labels of foods in which they are put. Few scientists, and certainly no non-scientists, can derive a sense of epicurean satisfaction from contemplating the words "butylated hydroxytoluene" on the list of goodies in a prepared snack. Such nomenclature heightens the conviction that we are surrounded by a sea of new synthetic chemicals even though our species has been sniffing and enjoying the odours of allyl isothiocyanate and diacetyl for many generations.

The new law should bring protection to workers in chemical factories. Vinyl chloride, kepone and dichloromethyl ether furnished three examples of inexcusable incidents in which such workers were exposed

Curbing chemicals

THOMAS H. JUKES

to toxic amounts of injurious chemicals. There is uncertainty and disagreement as to where the levels of such substances become tolerable, especially in the case of known or suspected carcinogens. However, it is known that the time of onset of cancer is lengthened by decreasing the dosage level, and lowering the dosage also decreases the probability that cancer will actually occur. These relationships apply regardless of whether or not an actual threshold can be established.

When the pressures for bans are examined and compared there are some interesting paradoxes. Polychlorinated biphenyls (PCBs) escaped scot-free for about eight years after it had been shown that they were environmental contaminants on a global scale, toxic at low levels to many vertebrates, and distributed without control. Their American manufacturer made small gestures such as taking PCBs out of "carbonless carbon paper". Their use continued in transformers and capacitors, which furnish, among other things, a comfortable living for the middle classes. But the fury of middle-class environmentalists descended on DDT, the use of which was primarily needed to save lives and prevent disease in disadvantaged countries. PCBs are far more stable than DDT and are known to be injurious to human beings as contaminants of cooking oil. Fortunately PCBs are on their way out, after being used as examples for the need of the new bill.

Let us hope that the aroused consciousness of possible injury from "new chemicals" will eventually result in a balanced study of hazards from both synthetic and "natural" compounds. In the meantime I am trying to avoid a feeling that I am endangering myself when I sniff the smoke of a camp fire.

Exotic viruses

SIR,—In last week's article on exotic viruses (page 625), an error was inadvertently introduced during the editorial work.

The identification of a Marburg-like agent announced two weeks ago was from material obtained from patients in a recent outbreak of illness in Zaire and the south of Sudan only.

Engineers' action

SIR,—In your Editorial of October 14 on the Institution of Chemical Engineers' report on Materials and Energy Resources you take that body to task for attempting "both to stimulate reasoned discussion on crucial resource problems" and trying "to get something done about them." But the professional engineer's job is precisely "to get things done", not simply to establish the truth; and planning ahead is part of his work. So, when a body of engineers, having closely surveyed a field in which they have specialised knowledge and competence, foresee a dangerous situation developing, it is their duty not merely to point this out but to make recommendations for action—in this case by the government. And if not they—who else?

You suggest, too, that in such long-term matters "the Working Party might have done better to look more closely for international solutions". But practically-minded engineers are more humbly concerned with what can be done here and now, even when

their sights are on the future; and their chances of influencing government thinking, upon which you set such a low value, are at least a great deal higher than the likelihood of setting the world to rights.

Exeter, UK*

Whale resources

SIR,—Dr Robert May (Sept. 9, page 91) gave an interesting commentary on the problems of managing whale resources vis-à-vis other items in the the relative values of the discount rate and the potential rate of increase of the resource is stressed. In this comparison the discount rate can be defined as δ where the present value of a whale caught in x years time is $e^{-\delta x}$ times the value of a whale caught today. May implies that δ is approximately equal to 'a', the interest to be expected from a deposit in a bank (10–20%).

In an age of inflation, and changing values of products from limited natural resources vis-à-vis other items in the economy, this may be misleading. The value in pounds of a whale at the time it is caught in x years time can be expressed as $e^{(b+c)x}$ times the present value, where b is the general inflation rate and c the rate at which the net value of products from a whale has changed differentially relative to average values of all commodities. b is positive and c may also be if prices for meat and other products from whales increase faster, and/or the price of fuel and other resources used in catching whales increase slower than prices in general.

The value of the discount rate to be used in determining the economic attractiveness (net present value) of a

whale caught later rather than now is given by $\delta = a - b - c$, which may not greatly exceed and may even be less than the rate of increase of whale stocks of around 5% annually. That is, to the extent that δ is less than a, the economic self-interests of a well-informed sole owner of a whale resource will conflict less seriously with conservation policies than implied by May.

The more important reasons for poor whale management have been the lack of an owner and poor information. While whales are common property, the individual whaling enterprise (company or even country) can ascribe little value to a whale in the future since there is no guarantee that it will be able to harvest that whale or its offspring. Also in the absence of well-funded research, whaling interests have been poorly informed of the longer term implications of management proposals. In the resulting fog of uncertainty about the future, their interests have naturally focused on the present and more clearly visible events. Both these effects have resulted in undue emphasis being given to maintaining current catches at a high level.

On another point, it seems unlikely, given the low (less than 10% per annum) rates of mortality and reproduction of whales that the unexpected changes in catch rates of fin whales mentioned by May is really indicative of population instability. It seems much more likely that with the small number of whaling expeditions now operating, the catch per unit effort is a poor and highly variable estimator of the abundance of whales in any particular area in a single season.

Destruction of stratospheric ozone?

from Michael A. A. Clyne

STRATOSPHERIC ozone will eventually be depleted significantly if releases of chlorofluoromethanes (CFM) continue at the present rates. Legislation is not necessary now, but if after no more than two years, existing evidence still supports significant ozone depletion, action to restrict manufacture should be taken by governments. These are among the main recommendations of the Committee on Impacts of Stratospheric Change, (*Halocarbons: Environmental effects of chlorofluoromethane release*, National Academy of Sciences, Washington DC, 1976) set up by the US National Academy of Sciences.

In 1974 I reviewed Molina and Rowland's article (*Nature*, **249**, 810) in the same issue of Nature, on the effect of chlorofluoromethanes on stratospheric ozone. Then, neither I nor most other scientists, believed that the hypothesis presented by Molina and Rowland, and independently by Stolarski and Cicerone (*Canad. J. Chem.*, **52**, 1610; 1974) would in fact develop into one of the most important recent issues in environmental pollution. Briefly, this theory, which has now largely been supported by an authoritative report of the US National Academy of Sciences (*Halocarbons: Effects on stratospheric ozone, Panel on Atmospheric Chemistry*, National Academy of Sciences, Washington DC, 1976), is as follows. CFM 11 (CFCl₃) and 12 (CF₂Cl₂), which contain chlorine, fluorine and carbon only, are produced in large amounts in all developed countries of the world. Approximately half of the total output is used as propellants in aerosol cans for

personal consumer uses (such as hairsprays and deodorants). Because of the stability that makes these compounds suitable for aerosol cans and for other uses, CFM 11 and 12 are very inert and no known major sinks for these compounds have yet been identified in the lower atmosphere (troposphere). Hence a large fraction of all past production of CFM 11 and 12, whether used for aerosols, car air conditioners or refrigerators is still present in the troposphere and indeed, these compounds will continue to accumulate there. Diffusion to higher altitudes occurs (Fig. 1), up to the stratosphere where most of the Earth's ozone (O₃) shield is located. The CFM can be photochemically dissociated there by far ultraviolet light at wavelengths around 190 nm. This light is not completely removed at stratospheric altitudes by the ozone and oxygen that normally filters out ultraviolet light, at wavelengths less than 300 nm, from reaching the Earth's surface. Photochemical action releases chlorine atoms from the CFM: and chlorine atoms react rapidly with ozone, giving chlorine monoxide (ClO) free radicals: $Cl + O_3 \rightarrow ClO + O_2$ .. (1). The reaction (1) is then followed at once by the rapid reaction (2) of ClO with the large quantities of the free oxygen atoms present at stratospheric altitudes between 25 and 50 km: $ClO + O \rightarrow Cl + O_2$ (2). Chlorine atoms are thus recycled, and are able to consume more ozone: this sequence is termed a chain reaction. Finally, the cycle is terminated by removal of chlorine atoms in their

reaction with methane

$$Cl + CH_4 \rightarrow HCl + CH_3 \qquad (3)$$

Most of the HCl formed in reaction (3) is not recycled back to active chlorine. Although many other reactions are involved, some of which are mentioned below, the overall effect of CFM is thus clearly to deplete stratospheric ozone. The NAS reports conclude that this description of the problem, essentially as advanced by Molina and Rowland, cannot be seriously questioned, although there are new factors that probably somewhat diminish the effect on ozone depletion that they calculated.

There is no justification for the total rejection of an effect of CFM on ozone depletion, which had been maintained earlier by a few scientists. In their report, the NAS Committee state that "Selective regulation of CFM uses and releases is almost certain to be necessary at some time and to some degree of completeness". In reaching their conclusions, the NAS were guided by a panel of distinguished experts including one Briton, Brian Thrush, and one German, Dieter Ehhalt. The report is an impressive document, containing a large amount of carefully sifted information that will be invaluable to future workers in atmospheric sciences. The approach is low-key, thoughtful and critical. The evidence accumulated by the panel is a formidable case in favour of an effect of halocarbons on stratospheric ozone. However, it is considered that the risks of a delay of not more than two years in restricting CFM releases are low. Although most scientists will probably agree with these views, some will doubtless point to the admitted wide margin of error in the estimate of a 7% eventual ozone depletion, with CFM 11 and 12 releases at the 1973 level. (According to the Panel, the limits of 2 to 20% ozone depletion have a 95% confidence level).

Some will say that the risk is slight, and that in any case industry is already reducing production of CFM 11 and 12, and is actively seeking substitutes that will have a shorter tropospheric life, and hence be less harmful. It re-
Fig. 1 The atmospheric ClOx cycle.

mains to be seen whether the search for acceptable substitutes for CFM 11 and 12 is sucessful; this is not likely to be an easy problem. CFM 22 (CHF₂Cl), among others, has promise as a substitute for CFM 11 and 12 in spray cans.

Other people will maintain that the risk is unacceptable, and that legislation is needed now rather than (possibly) in two years time. They will point to the possibility that delay might lead to politicians and governments losing sight of a problem which is effectively postponed for two years, a time scale comparable to intervals between elections. However, it should be noted that as well as studies by US government authorities, both the EEC and the West German government are initiating substantial investigations into the CFM-ozone problem.

The British government published their report on chlorofluoromethanes and their effect on stratospheric ozone earlier in the summer. This report was prepared by the Department of the Environment (DOE) with considerable assistance and guidance from AERE, Harwell. Their conclusions are broadly in line with those of the NAS report, although they do not recommend any specific regulatory action by governments. The DOE report is a useful summary of results; although clearly the resources that are evident in the NAS report were not available to the DOE compilers. The referencing of the DOE report is rather random and non-specific, and some literature citations are an encouragement to whimsical day-dreaming! For instance: ICI (1976), Imperial Chemical Industries, private communication. Dubreuilh W. (1896), des hypér-keratoses circonscrites; *Ann. Dermatol. Syphilig.* 3rd Series, 7, 1158-1204; quoted by Blum (1956).

In order to predict the effects of CFM on stratospheric ozone, a wide variety of data are required. The scope and uncertainties of these data varies enormously. Some of the basic types of information needed are (1) direct measurements of Cl atom, ClO radical, and other concentrations in the stratosphere; (2) the reaction rates of key elementary chemical reactions, as determined in the laboratory, and applicable to stratospheric temperature ($\simeq$ 220 K); (3) knowledge of the transport of air masses from the troposphere to the stratosphere. The first type of data (1), is perhaps the most important, because direct measurement of concentrations is the final check that the correct information under categories (2) and (3) is being used. Unfortunately, data of type (1) are by far the most difficult to obtain and are extremely sparse. The only results (so far) are *in situ* measurements of Cl and ClO

How rigid the nucleotide?

from a Correspondent

CRYSTALLOGRAPHERS have become used to seeing every structural idiosyncrasy they unearth in the crystal structure analysis of molecules of biological interest become a peg upon which the edifice of some molecular biological theory is hung. This has been particularly true for the study of the nucleotide and amino acid monomers from which nucleic acids and proteins are constructed. Beginning with the use of the covalent bond lengths and angles observed in monomers in the design of molecular models of these biological polymers, the results of crystal structure determinations have been extended to provide constraints which might properly be assumed for hydrogen bond geometry, for the conformations which can be expected to be preferred about various single bonds and, for the patterns of arrangement of water molecules and ions around biological polymers. This fertile field has been exploited with ever increasing confidence and perhaps nowhere more than in the analysis of the relationship between the properties and structure of nucleic acids. An important development in this work has been the rigid nucleotide concept

which suggests that mononucleotides have a rather rigid conformation which is conserved when they are joined together to form a polymer. X-ray diffraction studies of nucleotides, nucleosides and crystalline polynucleotides have provided a great deal of evidence for this although a number of recent X-ray single crystal studies of nucleotides have suggested that the situation may well be rather more complicated than was at first thought. The need for caution in applying the rigid nucleotide concept too insensitively is further emphasised by Evans and Sarma in a recent issue of *Nature* (**263**, 567; 1976). From NMR studies they suggest that adenine-containing nucleotides and the oligomers derived from them are no more rigid than the nucleoside adenosine itself. These studies are of course of particular interest because they relate to the situation in solution. An important application of the results of this work which is considered by the authors lies in the analysis of the structure of yeast phenyl alanine tRNA determined by X-ray single crystal studies and in particular the correlation of nucleotide conformation and base-stacking.

in the stratosphere from two balloon flights carried out by J. G. Anderson (University of Michigan) in summer 1976 at Palestine, Texas. Both concentrations of Cl and ClO were determined by Cl atom atomic resonance fluorescence, which has been successfully used also for O atom and OH radical measurements in the stratosphere, by Anderson (*Geophys. Res. Lett.*, **2**, 231; 1975; *Geophys. Res. Lett.*, **3**, 165; 1976). ClO radicals were reacted with nitric oxide to give Cl atoms, which were detected by atomic resonance fluorescence. The technique was adapted from flow methods for laboratory measurements of Cl atoms and ClO radicals that were developed recently (see Bemand and Clyne, *J. Chem. Soc. Faraday II*, **71**, 1132; 1975). Anderson's first Cl and ClO experiments have not so far led to satisfactory results, although the prospects for the atomic resonance and other methods look promising.

Additional direct verification is in principle obtainable from measurements of ultraviolet light intensity at ground level. Whilst such measurements have been made for a number of years, the natural variation of ultraviolet levels at the ground is large. The effects of CFM would probably only become observable in this way when

the ultraviolet level was already increased by a significant, probably unacceptable amount.

Data of type (2), the rates of chemical reactions, are considered carefully in the NAS panel report. One basic difficulty was to identify correctly the major reactions, of which there are a large number. The recently-proposed role of chlorine nitrate, ClONO₂, has necessitated the introduction of several new reactions. The elementary reaction rates of chlorine nitrate are not, however, all well-defined. Fortunately, the model for ozone depletion is not very sensitive to these rates, and some confidence may be attached to the NAS panel's conclusion that the ozone depletion is reduced by a factor of about 1.7 by inclusion of chlorine nitrate in the model.

The NAS panel conclude that the largest uncertainty in the ozone depletion model is due to uncertainties in the relevant chemical reaction rate constants. They carefully identify the reactions introducing the greatest uncertainty as

$$OH + HO_2 \rightarrow H_2O + O_2$$
followed by
$$OH + HCl \rightarrow H_2O + Cl.$$
These reactions are involved in the sink processes by which active chlorine

(Cl and ClO) is removed from the ClO_x cycle. Surprisingly, the two reactions of the ClO_x cycle, that is $Cl + O_3 \rightarrow ClO + O_2$ and $O + ClO \rightarrow Cl + O_2$, do not introduce large errors, because their rates have been carefully measured in the laboratory. The first measurements of $Cl + O_3$ and $O + ClO$ rates by Bemand, Clyne and Watson at Queen Mary College in 1973 (see *J. Chem. Soc., Faraday I,* **69,** 1356; 1973; Clyne and Watson, *J. Chem. Soc. Faraday I,* **70,** 2250; 1974) have been only slightly altered as a result of subsequent work in the USA and in this laboratory.

Significant uncertainty ($\pm$ a factor of 1.7) in the prediction of ozone depletion is also introduced by the one-dimensional model used by the NAS panel to approximate the distribution and transport of the chemical species involved. This model is equivalent to averaging the concentrations, motions and chemical reactions over latitude and longitude, leaving only their dependences upon altitude and time. This approximation is considered to be a

good one. For instance, the equivalents of averaged gas transport rates appear in the model as the vertical eddy mixing or transport coefficient, which depends only on the altitude.

One further very important question concerns the effects of an increased ultraviolet intensity (UV-B, 280 to 320 nm) at ground level on animals and plants. The biological effects of UV-B are not as extensively dealt with by the NAS reports as are other aspects. This may be due to the relative lack of knowledge in this area. It is clearly to be identified as a priority area for future work on the CFM-ozone problem. However, in general terms, the deleterious effects of UV-B radiation on living cells are well known. For example, there is a clear causal connection between the more common (but less serious) forms of skin cancer (basal and squamous cell carcinomas) and UV-B exposure. The connection between the less common, but often fatal malignant melanoma and UV-B, is suggestive but not certain, according to

the NAS report.

Release of pollutants other than CFM, which can also affect ozone levels, is another topic requiring extensive future work. Among halogen compounds, further work on methyl chloride formed by the burning of vegetation, is indicated. Also, Crutzen has suggested that methyl chloroform (CH_3CCl_3), whose manufacture as a degreasing agent is considerable and possibly increasing, may eventually cause ozone depletion comparable to that of CFM 11 and 12. Bromine compounds, released for example as methyl bromide in soil fumigants, are probably not produced in large enough quantities to have major effects. However, Br atoms and BrO enter into a similar, but more effective cycle to that of Cl and ClO.

$$Br + O_3 \rightarrow BrO + O_2, \quad O + BrO \rightarrow Br + O_2.$$
The rate constants for the bromine reactions are not particularly well known. Nitrous oxide, apparently re-

---

Cultivation of human malaria

from F. E. G. Cox

THE *in vitro* cultivation of malaria parasites has been possible for many years but only one or a few successive cycles of development have been achieved and these successes have been mainly with the malaria parasites of monkeys. The amount of physiological and biochemical knowledge that has accumulated from such studies has been vast and it cannot be disputed that much of it is directly or indirectly applicable to chemotherapeutic and immunological studies aimed at the control of malaria. What is desperately required, however, is the long term continuous cultivation of human malaria parasites which cannot be maintained in standard laboratory animals. For some time now there have been rumours of the successful cultivation of *Plasmodium falciparum* in the United States and now two independent reports have appeared, giving the long-awaited experimental details (Trager and Jensen, *Science,* **193,** 673; 1976; and Haynes *et al.,* page 767 in this issue of *Nature*). There can now be no doubt that the continuous cultivation of *P. falciparum* can be achieved in simple media and that it should shortly be possible to obtain the yields of parasites necessary for the production of experimental vaccines.

Both media are remarkably simple. Trager and Jensen use a modification of an earlier medium (RPMI 1640 with HEPES buffer and serum) for the cultivation of *P. coatneyi* from monkeys (Moore *et al., J. Am. med. Ass.,* **199,** 519; 1967) but substitute human serum for the monkey serum originally used. In essence, the medium

flows over a shallow bed of red blood cells which are disturbed as little as possible in an atmosphere of low O_2 and high CO_2. The technical details are still being modified and Trager and Jensen began by using 7% CO_2 and 5% O_2 but changed this to 1% O_2 in later experiments with better results. The technique of Haynes *et al.* is more traditional, involving a supplemented medium 199 with 1% foetal bovine serum in an atmosphere of 3% CO_2. No doubt many other ways will be found to grow *P. falciparum,* and Trager and Jensen report success using their medium in a candle jar (a container in which a candle has burned and extinguished).

The most important features of the cultivation techniques described seem to be the high levels of CO_2 and the fact that the number of red cells infected rarely rises above 1%, thus preventing the culture medium from becoming too acidic as a result of the metabolic activities of the parasites, which is a problem inherent in this kind of experiment. Although the multiplication of parasites recorded is low (a four-fold increase per cycle is assumed by Trager and Jensen) the numbers of parasites available for collection can be considerable if parallel cultures are set up and initiated from diluted cultures

at the end of each cycle. Haynes *et al.* obtained eleven successive cultures and Trager and Jensen more than twenty-five (and Trager has since reported continuous cultivation over 105 d, implying fifty or more cycles) so there is no reason why such cultures should not be maintained indefinitely.

The technique described by Trager and Jensen looks more promising than that of Haynes *et al.,* but the latter authors have made a major advance by showing that their cultures can be initiated from frozen blood samples. It should therefore be possible to initiate a culture and to freeze stabilates from that culture for the initiation of others. This would save the lives of countless owl monkeys (*Aotus trivirgatus*), which at the moment are the only sources of laboratory maintained *P. falciparum,* and also standardise experiments carried out in different laboratories.

The implications of these experiments are considerable, for as well as the biochemical and physiological observations which are now made feasible it should be possible to grow the numbers of merozoites (the stages that pass from one cell to another) needed for producing vaccines. The only homologous vaccine with real potential, in monkeys at least, is that based on merozoites (Mitchell, Butcher and Cohen, *Immunology,* **29,** 397; 1975) and the production of a suitable vaccine free from viruses is only possible from cultured parasites. With 96 million cases of malaria each year and with *P. falciparum* being the major killer the production and evaluation of such a vaccine should not be delayed.

leased by bacterial action on nitrogenous chemical fertilisers, is fairly stable in the troposphere. The possibility of this compound affecting stratospheric ozone levels should certainly be studied.

All in all, the ozone layer is fragile, and wide-ranging long-term studies of possible effects of pollutants not yet identified are essential. This should include the acquisition of more information on ozone reaction rates. Exclusive concentration on CFM 11 and 12 effects is unwise, since it is quite possible that other deleterious compounds may be present now, or at some future time, due to shifts in industrial production.

I have emphasised here the effects of CFM on the ozone layer and the consequential increase in UV-B radiation at the Earth's surface. It should also be noted that other climatic changes due to CFM cannot be excluded. For instance, Ramanathan (*Science*, **190**, 50; 1975) has stated that CFM 11 and 12 are sufficiently effective absorbers of infrared radiation (near 10 μm) to have a potentially significant effect on the Earth's heat balance.

The role of British science in the CFM-ozone problem is an important one. Much of the basic work leading to the original theories of Stolarski and Cicerone and Molina and Rowland, was carried out in the UK. Lovelock developed a sensitive electron-capture gas chromatograph, with which he was able to demonstrate the presence of various halocarbons arising from man's activities, and to obtain measurements of CFM 11 and 12 at various locations. The programme of work (COMESA) sponsored by the Department of Trade, and carried out partly in university laboratories and partly by the Meteorological Office on possible effects (slight) of Concorde on the stratosphere also

provideed valuable input data for the CFM-ozone problem. Current initiatives in the CFM-ozone problem are being taken by industry; research on both CFM 11 and 12 effects, and on substitute CFMs is being carried out. Basic science relevant to stratospheric ozone is being supported by the Science Research Council, and recently the Natural Environment Research Council has announced its intention to concentrate more resources on atmospheric science. The financially small but scientifically significant support over many years in this area by the Royal Society through its Gassiot committee has also been very valuable.

With this expertise available, it is sad therefore that there is no sign at present that the British government is planning any major programme of investigation in stratospheric science related to the CFMs and ozone, although it does contribute through the EEC organisations to the European effort. No more than £100,000 would probably be allocated to such a new investigation, if mounted eventually by the Department of the Environment. Although the restraints of the present economic situation have to be acknowledged, it is a pity, nevertheless that it was not possible to use the experience gained in the COMESA research as the basis of an ongoing and centrally-planned programme of work on atmospheric pollution.

There is a message from all this for those who ask for more "relevant" research programmes, related to current needs of society. Without the undirected, basic research programmes which were carried out, the chances are that the risks to ozone from CFMs would not have been identified until much later, if at all. Identifying the problem is a large part of finding the solution. □

sequences in pure form, by cloning in a bacterial host, has opened up the possibility of studying the sequences flanking the gene which may be important in regulation, and which cannot be obtained sufficiently pure for sequence studies by any other means. The sea urchin (*Psammechinus*) histone gene repeat unit has been cloned in phage lambda and some 25% of the nucleotide sequence determined by a group at the University of Zurich (Walter Schaffner).

The mammalian globin genes are also under determined attack in several laboratories. Charles Weissman (University of Zurich) and Richard A. Flavell (University of Amsterdam) reported the partial purification of the + and − strands respectively of rabbit globin DNA. Weissman and colleagues have isolated the + strand by hybridisation to immobilised globin cDNA; the − strand has been isolated by hybridisation with mercurated mRNA. The final purification step will be to hybridise the two strands, since only complementary sequences should anneal. This reconstituted DNA inserted into a plasmid should provide a source of the complete globin gene sequence including the flanking non-transcribed regions.

Still looking to the future, Bob Williamson (St Mary's Hospital Medical School, London) described a possible use for cloned globin gene sequences as chain-specific probes for the study of certain inherited defects such as the thalassaemias.

Recombinant DNA is also a powerful new tool for probing the immunoglobulin genes. As the first step to tracing changes in the Ig-gene coding sequences predicted by the theory of somatic mutation, Bernard Mach and colleagues (University of Geneva) have constructed plasmids carrying cDNA copies of a mouse myeloma light chain mRNA. The Geneva group has obtained plasmids containing constant and variable region sequences both separately and together. Hybridisation studies have shown that the untranslated region in kappa light chain messenger from different sources is highly conserved.

However, these experiments exemplify some of the conjectural risks which have caused concern about this type of work. The mRNA was not pure and indeed 40% of the initial recombinants contained unknown sequences. More worrying still is that myeloma cells are known to express C-type RNA viruses and that the plasmid carried a drug-resistance marker containing an IS sequence.

This problem is avoided in work from the Laboratory of Molecular Biology in Cambridge reported by Terry Rabbitts. Light chain mRNA

Nuts and bolts of genetic engineering

by Eleanor Lawrence

> The Biochemical Society's 9th Harden Conference, entitled the Role of Recombinant DNA in Molecular Biology, was held at Wye College on September 20–24, 1976.

IN the present state of the art, a meeting on *in vitro* recombinant DNA must of necessity concern itself more with means than ends. This is partly a result of the need to develop and refine a range of completely new techniques; but it is also a consequence of the almost unique situation in which the novel technology has been applied less

than whole-heartedly, as a result of the voluntary postponement of some experiments until experimental conditions minimising the hypothetical safety risks of this work had been agreed.

But now that experimental guidelines have been published in the United States and Britain, workers are preparing to clone genes from everything from maize to man. A foretaste of the power of these new techniques to investigate otherwise unapproachable problems of the organisation of the eukaryotic genome was given at the meeting.

The ability to obtain specific gene

from myeloma cells can be reverse transcribed into cDNA by starting with a hexanucleotide primer T_2G_3T that has been shown to prime only at a site just within the 3' end of the C region. In this way pure fragments containing the immunoglobulin V and C coding sequences only can be made, without the need for constructing plasmids by way of impure mRNA. A comparison of the reverse transcriptase "stutter" pattern of mRNA from a mouse T-cell lymphoma has produced evidence that in these T cells the immunoglobulin genes are at least transcribed.

The most elegant exploitation of the recombinant DNA technology was in work by David Hogness's group (Stanford University) on the organisation of the *Drosophila* chromosome. Taking advantage of the relatively small size of the *Drosophila* genome and the availability of polytene chromosomes, they have constructed plasmids containing different *Drosophila* gene sequences which have been mapped on the chromosomes. Hogness described analyses of the histone genes, the genes induced by 'heat shock', and of a sequence coding for an abundant mRNA. It is particularly intriguing that this mRNA sequence is found by *in situ* hybridisation to be located at 33 sites dispersed throughout the genome. What the dispersed gene sequence means in terms of evolution and control is still a matter for dispute. Hogness tends to the view that each individual sequence will be expressed in a different cell type, which would explain the maintenance of 33 separate sequences coding for the same product.

For those who wish to study the functional expression of eukaryotic genes, cloning in plasmids or phage has one overwhelming disadvantage. So far there are only a few reports that eukaryotic genes can be expressed in bacteria. Also, there will eventually be a need to put characterised, specfically mutated genes back into eukaryotic cells to study their expression. This might be done using animal tumour viruses that can integrate into mammalian cell chromosomes.

The potential of SV40 as an 'eukaryotic vector' is at present being explored and Paul Berg (Stanford University) described the construction of an SV40 vector in which the late genes have been deleted, and its use to clone fragments of lambda DNA in monkey cells. Additional vectors are under construction in which the early region has been deleted; these may more readily allow transcription of the inserted DNA. All these SV40 vectors are dependent on a temperature-sensitive helper virus for growth.

In this system there is however an ultimate constraint on the size of the inserted DNA because of packaging into SV40 protein coats of defined size. This problem may be overcome in a system that Joe Sambrook (Cold Spring Harbor Laboratory) is developing. He has found that human cells transformed by SV40 virus or DNA contain a large number of free SV40 DNA molecules. Transformation rather than plaque formation could be used as the selective marker for recombinants, and since no helper virus is needed and no infectious virus is released less rigorous containment conditions are required.

A system in which cloned eukaryotic DNA might be transcribed and translated was described by Janet Mertz (Laboratory of Molecular Biology, Cambridge). Both prokaryotic and eukaryotic DNA injected into the nucleus of *Xenopus* oocytes appear to be reconstituted into chromatin and transcribed but whether the transcripts are sensible or are translated is still problematical. One use for this system would be in identifying eukaryotic promoters by fragmenting well-characterised genes and then determining which pieces are transcribed.

So far most attention has been focused on the use of restriction enzymes for mapping gene sequences and producing recombinant DNAs. But there is another side to the story as pointed out by Adrian Bird (MRC Mammalian Genome Unit, Edinburgh) who has been studying the natural methylation of some restriction targets, in the ribosomal DNA of *Xenopus laevis*, which renders them resistant to attack. By analysis with a set of restriction enzymes he has shown that the probability of methylation at each suitable site is high (0.99) but that there is a unique site within the rDNA repeating unit that remains unmethylated in up to half of repeats. He has also shown that the pattern of methylation is copied onto newly synthesised DNA *in vivo* and so is inherited by a daughter somatic cell from its parent.

The prospect of using eukaryotic genes cloned in bacterial cells to make large amounts of valuable gene products is still very much in the future. But Noreen Murray (University of Edinburgh) described ways of harnessing the enormously efficient lambda leftward promoter to provide enhanced expression of inserted bacterial genes, a technique which could be applied to produce large amounts of many useful phage and bacterial enzymes.

Although the issue of containment levels and possible safety risks hardly surfaced officially, safer experimental procedures were much on everyone's mind. Paul Berg expressed concern that antibiotic resistance was still so widely used as a selective marker since

it could contribute to the persistence of any escaped vector, not only in the human intestinal tract but in the general environment (Sydney Brenner has been quoted as remarking that the world is a dilute solution of tetracycline). The proliferation of different vectors for cloning recombinant DNA also led Berg to propose a register clearly setting out their desirable and undesirable features (such as the possession of insertion sequences). Berg said that he would collate a list, from names and addresses sent to him, of people working with vectors. This would be published in *Nucleic Acid Recombinant Scientific Memoranda*, produced by and available from the National Institutes of Health. □

Actins plural

from Dennis Bray

The impersonal air that is usual in a comment like this wears thin when its author is forced to eat his words. For it was indeed I who solemnly predicted, three years ago, that the actin present in different kinds of cells was one and the same gene product (Bray, *Cold Spring Harbor Symp. quant. Biol.*, **37**, 567; 1973); and in this I could not have been more wrong. Hardly were the words out of my mouth when new forms of actin began to spring up like mushrooms. So well they grew, and in such numbers, that little remains now but to turn to Philosophy and learn the value of the refutation of a cherished hypothesis. (Popper, *The Logic of Scientific Discovery*, Hutchinson, 1959).

It has always been clear that the actin and myosin of non-muscle cells must behave in a different fashion to that of muscle: the exigencies of motility and cell division ensure that. But evidence for differences in amino-acid sequence, rather than in the modifying influence of ancillary components, is harder to come by. Some early hints exist in the literature, such as that in Fig. 12 of a paper on the actomyosin from brain (Berl and Puszkin, *Biochemistry*, **9**, 2058; 1970). This shows that brain actin and muscle actin run differently on urea-acrylamide gels and seems to have been overlooked in recent papers that present the same fact (Storti and Rich, 1976, *Proc. natn. Acad. Sci. U.S.A.*, **73**, 2321; 1976; Storti, Coen and Rich, *Cell*, **8**, 521; 1976). But it was probably in the course of a thorough examination of platelet actin, that the first unambiguous differences—in the form of cyanogen bromide peptides—were found (Booyse, Hoveke, and Rafelson, *J. biol. Chem.*, **248**, 4083; 1973). A later comparison of peptides from brain actin to those from muscle also showed differences (Gruenstein and Rich, *Biochem.*

biophys. Res. Commun., **64**, 472; 1975).

At this point it was still possible, with difficulty, to believe in one actin. The cyanogen bromide evidence was clear, but perhaps there had been an incomplete cleavage. Criticism of the work on brain actin was possible, since the data showed as much variation between different samples of muscle actin as between muscle and brain. But there was little point in chopping these actins down: no sooner the attempt than two stood where previously there had been but one! (Dukas, *The Sorcerer's Apprentice*, 1897). Evidence was adduced, first for platelets and then for other cells, that not only was their actin distinct, but it was multiple. The platelet actin that Booyse and his collaborators studied was extracted as if it was muscle actin, and it obligingly behaved in this way. But this was only a small fraction of the total actin and when a different approach was tried, a protein with a quite different ability to polymerise was obtained. (Abramowitz, Stracher, and Detwiler, *Arch. Biochem. Biophys.*, **167**, 230; 1975). Moreover amoeba, fibroblasts and brain, also give small amounts of polymerisable actin, or large amounts of unpolymerisable actin, according to the extraction used. There is still a lurking question of whether a slight denaturation is involved, but on the face of it this is evidence for two actins.

An even greater virtuosity is apparent in developing muscle which shows no less than three actins (Whalen, Butler-Browne, and Gros, *Proc. natn. Acad. Sci. U.S.A.*, **73**, 2018; 1976). The evidence here is from gels lacking SDS—and it must be recalled that in some conditions even pure muscle actin wil split into a number of bands (Pardee and Bamburg, *J. Neurochem.*, **26**, 1093; 1963; Carsten and Mommaerts, *Biochemistry*, **2**, 28; 1963)—but the changes that accompany differentiation are convincing. Finally, lest there are any lingering doubts about the reality of the differences considered, comes definitive evidence from the amino acid sequencers: slow, but exceedingly hard to demolish. With the complete sequence of muscle actin in hand, Elzinga and colleagues have now compared peptides from human heart and human platelet actin (Elzinga, Maron, and Adelstein, *Science*, **191**, 94; 1976). A diminutive difference exists—1 residue in 29 is changed, from a harmless valine to an innocuous threonine—but it is enough.

From the wider biological standpoint these results add to other examples in which closely related proteins are used to perform similar, but distinct, functions. The evidence available for tubulin suggests that the various organelles in which this protein appears are based on different gene products;

and a similar statement probably holds for myosin and tropomyosin. Undoubtedly there are advantages in this: the process of gene duplication is familiar in haemoglobin, and provides a ready-made protein on which evolution can go to work. But, if Cassandra is allowed one parting shot, in the matter of the disposition of these proteins within the cell many mysteries remain. It seems scarcely credible that such similar molecules could be moved within the same small space and yet not cross-react or finish in the wrong place.

Southampton model fair

from N. MacDonald

A research conference on nonlinear mathematical modelling was held at Southampton University on September 13–17, 1976. It was sponsored by the Social Science Research Council and organised by D. R. J. Chillingworth, H. B. Griffiths and D. A. Rand of the mathematics department at Southampton.

FROM the viewpoint of a physicist working on non-linear modelling in biology, the most satisfying talks dealt with specific problems from the hard sciences, handled with mathematical sophistication. There has been much interest recently in the behaviour of travelling waves in solutions undergoing oscillatory chemical reactions, such as the Zhabotinskii reaction, both as objects of study in themselves and as a possible paradigm for pattern formation in organisms. N. Kopell (Northeastern University, Boston) described two elegant applications of bifurcation theory, to the outward propagation of chemical waves from a centre, and to the collision of two such waves.

A considerably deeper physical problem was the subject of a fascinating lecture by G. Jona-Lasinio (University of Rome). He described recent work by the Russian mathematicians Bleher and Sinai on phase transitions (*Commun. Math. Phys.*, **45**, 247; 1976; see also a review by Jona-Lasinio in *Nuovo Cimento*, **26B**, 99; 1976). These are difficult phenomena to model because one has to build up from local assumptions about interactions between atoms to an essentially collective large scale switch in the behaviour of the material. Bleher and Sinai treat this scaling process as an iterative operation on the probability distribution. The asymptotic large scale forms of the probability distribution are obtained as the fixed points of a discrete dynamical system on a function space, and phase

transitions are related to the bifurcations of these fixed points.

The bifurcation theory of discrete dynamical systems is a very popular subject at present. The great richness of the behaviour of solutions of even the simplest difference equations (discrete dynamical systems on the real numbers) was the subject of a recent review by R. M. May (*Nature*, **261**, 459; 1976). At this meeting J. Guckenheimer (University of Santa Cruz) described the application of this kind of mathematics to a model of the population fluctuations in the famous blowfly experiment of Nicholson.

Turning to the more qualitative surveys, B. Goodwin (University of Sussex) discussed morphogenesis, in particular recent results on the circumferential field in the development of the insect limb. He stressed the gap between the field concept, which is effective in coordinating data, and the underlying mechanisms, as well as that between the abstract dynamics suggested by catastrophe theory and the observable expression of form in the organism. Evidence that the conceptual difficulties involved in understanding complex biological systems are of a different order from the mathematical difficulties of current modelling techniques, came in the lecture by R. Rosen (Dalhousie University).

Several of the lectures on the social sciences had some common themes. A. C. Renfrew (Southampton University) dealt with attempts to set up a framework in which questions about the growth and decline of cultures can be handled by dynamical modelling techniques, analogous to those of the Forrester–Meadows group. K. L. Cooke (Pomona University, California) described the application of one such method to Renfrew's description of the Aegean culture. A. G. Wilson (University of Leeds) gave an account of the great variety of modelling techniques that have been applied to urban geography, and stressed the need to move on to a more integrated approach.

P. J. Harrison (University of Warwick) discussed the problem of short term prediction in economic and social contexts. Here standard methods apply essentially to linear behaviour, while the need to handle non-linearity becomes apparent especially when concerned with the need to keep options open for the possible reversal of an existing policy.

Although the main aim of the meeting was to set up an interaction between pure mathematicians and modellers, it was evident that cross-disciplinary contacts between modellers were equally stimulating. These were mainly informal, although some structure was given by a series of meetings in the archaeology department. All

open-minded members of the conference must have taken away, as well as their copies of Poston and Stewart's little red book, and the good resolution to think more geometrically, much benefit from the chance to talk with people from a remarkably wide range of disciplines. □

Venus is another differentiated planet

from G. Fielder

MANY scientists were surprised to find that the Moon was a differentiated planet. Now, *in situ* measurements of parts of the surface layers of Venus have indicated that the Earth's "sister" planet is more like the Earth than the Moon in its radioactive element content. Whereas measurements of the potassium, uranium, and thorium concentrations made in October 1975 using Veneras 9 and 10 indicated the presence of basaltic type rocks, earlier results from Venera 8 (July 1972) had indicated the presence elsewhere of rocks similar in their radioactivity to that of a typical terrestrial granite.

Writing with K. P. Florenskii, A. T. Bazilevskii and A. S. Selivanov in *Doklady Akad. Nauk. SSSR* (**228**, 570; 1976) the late A. N. Vinogradov has reported studies of the photographic panoramas and other data transmitted from Veneras 9 and 10 by way of a relay satellite. Telecameras mounted 1 m above the surface took high Sun photographs, including the one reconstructed in Fig. 1, with a resolution of about 1/3 degree. So effective was the

dense atmosphere of Venus in diffusing the weak light at ground level that high contrast versions of the photographs show "artificial shadows" which always point towards the appropriate camera.

The upper right hand corner of Fig. 1 shows the skyline, estimated to be several tens of metres distant. The sharpness of the skyline indicates a fairly high atmospheric transparency and, consequently, a comparatively low dust content. If any wind had been blowing across the surface when the pictorial data were transmitted, the wind had not been dust laden. Nevertheless, the authors have suggested that the clod-like nature of the dark soil filling the spaces between the numerous rock blocks may have resulted, in part, from the evacuation of fine particles by a weak wind. An alternative explanation, they suggest, is that the clods were produced following hydration of the particles.

Typically, the rock blocks themselves have dimensions of some tens of centimetres. Some are angular, others rounded. Many indicate that they have been detached from hard, layered bedrock. Others, which appear to be mostly buried, could even be outcrops of bedrock. A few rocks have cracks which cross the bedding plane. Others appear to be vesicular.

Together with the knowledge from radio observations that the surface layers of Venus are underdense, the picture data establish that certain dynamic processes are in operation there now. If the corrosive agents hydrochloric acid and hydrofluoric acid observed in the upper atmosphere of Venus are present at ground level they could be an important factor in the rounding and disintegration of the

rocks to generate the soil. Whatever the predominant mechanism of denudation on Venus, it is clear from the abundance of sharply sculptured rocks on the surface where Venera 9 landed that this is a geologically young area of the planet.

The clouds of Venus, which prevent our viewing its surface directly, are found at up to 70 km above the surface. Most meteoroids of the present day populations would probably disintegrate in the thick, dense atmosphere (97% CO_2) before reaching the surface so that recent disturbances of the rocks of Venus are likely to be of internal origin. Now that two panoramas of the surface of Venus have shown scenes not unlike those of terrestrial desert landscapes, the next step will be to discover the processes which moulded the landforms of Venus. □

Fig. 1 Part of Venera 9 panorama. The rotation axis of the telecamera was inclined at ~40° to the vertical axis of the landing stage. The rocks shown here lie on, and form, a steep slope (the on-board inclinometer reading was ~30°). Data auxiliary to the picture data were transmitted in vertical bands which have been removed.

So Madagascar was to the north

from Peter J. Smith

IN a recent article on the Madagascar controversy, Kent and Tarling (*Nature*, **261**, 304; 1976) were adamant in claiming that "the Madagascar controversy still lives". They were right of course, even excluding the element of self-fulfilling prophesy. To expect everyone to accept that "palaeomagnetism has provided the definitive answer" to the Madagascar problem (*Nature*, **259**, 80; 1976) was evidently overoptimistic, or at least premature. The controversy does indeed live. But for how much longer in the light of a new palaeomagnetic analysis from McElhinney *et al.* (*Geology*, **4**, 455; 1976)?

The long-standing argument is, of course, over the geographical position of Madagascar before the breakup of Gondwanaland. Did this large island lie in the coastal embayment of Mozambique some 4° south of its present position? Or was it about 15° north, adjacent to the coast of Kenya-Tanzania-Somalia? Or has it always been where it is with respect to Africa, except perhaps for just a small amount of eastward drift? The answer is critical in defining the fit of eastern and western Gondwanaland. Evidence of various types has been adduced in favour of all three positions at various times, although clearly no more than one of the options can be correct.

The problem seemed well on the way to solution earlier this year when Embleton and McElhinney (*Earth planet. Sci. Lett.*, **27**, 329; 1976) presented palaeomagnetic data supporting the southward drift of Madagascar—

that is, a predrift position to the north. But Kent and Tarling were not so sure, citing a major geological argument against a northern position. In the vicinity of Kenya-Tanzania there are thick sediments apparently deposited from the Upper Carboniferous onwards, both onshore and out to several hundred kilometres offshore. So how, Kent and Tarling asked, could these deposits "exist in their present position if this was occupied by a microcontinent that has since moved away"?

They then went on to question both the validity of the palaeomagnetic data and the significance of the analysis based on them. The point about validity hinged on whether or not the measured sediments had been remagnetised since they were laid down. But Kent and Tarling argued that even if remagnetisation could be ruled out and the data were perfectly valid, there is at least one alternative way of comparing the Madagascar data with those from other landmasses. And this other way suggests that a southward drift of Madagascar is no more likely than a northward drift or no drift at all. The point was not that one method is any better or worse than the other, but simply that both are equally valid and reasonable.

Be that as it may, there is now a sequel. Since Embleton and McElhinny reported their first data, palaeomagnetic investigations of Madagascan rocks have continued (both in Australia and France) to the point where there is now an almost complete palaeomagnetic coverage of the Karroo Supergroup from the Upper Carboniferous to the Middle Jurassic. And all of the results have been brought together and analysed by McElhinny *et al.*

The Madagascan data fall into three sets covering, respectively, the time-spans: (1) Upper Carboniferous to Lower Permian, (2) Upper Permian to Lower Triassic and (3) Middle Triassic to Middle Jurassic. Unfortunately, appropriate African data are heavily biassed towards the Middle Triassic-Middle Jurassic, which makes comparison over the total Karroo period difficult.

And the results of the comparison are striking. Taking the time-spans (1), (2) and (3) together, the average angular difference between the Madagascan and African–South American pole positions is 16.8° for Madagascar in the southern predrift position and 15.3° assuming the island to have maintained its present position. These are palaeomagnetically significant differences. By contrast, the average angular difference for Madagascar in the northern predrift position is only 4.5°, which is palaeomagnetically insignificant. Moreover, these averages conceal

no anomalies; time-spans (1), (2) and (3) taken separately each give a similar result.

In short, the palaeomagnetic case for the northern predrift position of Madagascar is, in the word of McElhinny and his colleagues, "unequivocal". Even the sceptics must surely agree that at the very least the case is strong. It is difficult to believe that the palaeomagnetic data are not valid. Remagnetisation, for example, is possible, but hardly likely in view of the similar results for the three time-spans and the number of different rock types involved. So it would appear that someone has a lot of reconciling to do. □

Competition and sexual dimorphism in plants

from Peter D. Moore

As members of a species in which males and females are increasingly coming into competition with one another, it is interesting for us to consider the evolutionary consequences which have resulted from such a state of affairs in other species. Sexual dimorphism is the term used for situations in which the male and female of a species are adapted so that they draw on different resources, or tap a resource in different ways. It results from conditions where the limitations of the environment can produce deleterious competitive interactions between males and females inhabiting the same area.

Sexual dimorphism is quite common among animals and may result in considerable differences between the sexes. In many birds of prey, such as the sparrow hawk (*Accipiter nisus*) the male is considerably smaller than the female. The two sexes feed on different prey species, the male concentrating on smaller, more agile species, and the female on larger ones.

Among plants, very few examples of sexual dimorphism have been described. Obviously it could exist only within dioecious species, where the sexes are separate. One example is the sheep's sorrel (*Rumex acetosella*) which was studied by Putwain and Harper (*J. Ecol.*, **60**, 113; 1972). Here the two sexes were found growing together, but showed considerable differences in their times of growth and in the allocation of food reserves. Male plants grew faster in the spring, but expended less energy on the production of inflorescences and pollen than did the female on seed production. Female plants were later in their growth, but finally developed a taller canopy. Males

invested more energy in the production of roots and vegetative offshoots. Males and females thus tap the environmental resources at different times and in rather different ways, constituting an example of niche diversification between the sexes.

Freeman, Klikoff and Harper (*Science*, **193**, 597; 1976) have examined several dioecious plant species in relation to soil moisture in arid to semiarid habitats in Utah. They found that the ratio of male : female plants in all species examined varied with environmental conditions, mainly water availability. For example the meadow rue (*Thalictrum fendleri*) had a male: female ratio of almost 7 : 1 in dry sunny positions, whereas in moist shady conditions it was nearer 1 : 4. Mormon tea (*Ephedra viridis*) had a male : female ratio of 1.6 : 1 on steep, arid slopes and about 1 : 2 on alluvial bottomlands. The salt grass (*Distichlis spicata*) gave a ratio of about 3 : 1 in very saline conditions and about 1 : 1.5 in moderately saline areas.

These data suggest that males of all these species survive better than females in conditions of water stress, whereas the reverse is true where water is more available. Alternatively, sex determination may be environmentally controlled. Whatever the cause of this state of affairs, Freeman *et al.* suggest that the differentiation of niches between the sexes has adaptive significance. Reproductive success in males in these wind-pollinated species may be enhanced by their being located on exposed, dry ridges. Seed output from females, on the other hand, would be greater in conditions of improved water supply, especially later in the season.

They have not examined the role of vegetative reproduction in determining sex ratios. Putwain and Harper showed the importance of this influence in their *Rumex* studies and it is possible that resource allocation to vegetative reproduction in these species varies between the sexes and is differentially affected by water availability. *Ephedra*, for example, spreads extensively by vegetative reproduction. Niche differentiation between the sexes of these plants has evidently occurred in response to a selective pressure, but the precise physiological or morphological cause of the variations in sex ratio remain unclear.

Dioecious plant species are not uncommon and it will be interesting to see whether more of them exhibit sexual dimorphism. Sex ratios in populations, however, may not always be the best guide to dimorphism in plants because of the influence that vegetative reproduction can have by redressing the effects of differential germination and survival. □

review article

Transposable genetic elements and plasmid evolution

Stanley N. Cohen*

Transposable elements of DNA that are structurally defined and genetically discrete units seem to have an important role in the evolution of bacterial plasmids. Recombination occurring at the termini of such elements can result in the joining together of unrelated DNA segments that lack extensive nucleotide sequence homology. In addition, transposable elements serve as novel biological switches capable of turning on and off the expression of nearby genes as a consequence of their insertion into or excision from plasmid genomes.

ALTHOUGH the existence of plasmids in bacteria has been known for more than two decades, the extraordinary prevalence and biological diversity of these extrachromosomal genetic elements has been appreciated only recently. Plasmids were first identified in the Enterobacteriaceae, but subsequently have been found in almost every bacterial group where they have been searched for. Naturally-occurring plasmids vary in size from the 2,250-nucleotide-long minicircular "cryptic" plasmid of *Escherichia coli* strain 15 (ref. 1) to the large and complex F′ plasmids[2], which may contain more than 400,000 nucleotide pairs and carry up to 600 genes. A wide variety of biological functions is specified by plasmids (Table 1).

The essential feature common to all plasmids is a replication region capable of propagating itself and any genes linked to it. Presumably, early steps in plasmid evolution involve the assembly of deoxyribonucleotides to form a site for initiation of DNA replication (the replication origin) and acquisition of genes that specify functions required for autonomous replication. Subsequent linkage of the resulting replication segment to one or more genes that provide a biological advantage to cells carrying the plasmid would be expected to aid its propagation. Later steps in the evolution of some plasmids might involve the addition of groups of genes that facilitate inter-bacterial transfer or an extracellular existence. Thus, in this evolutionary continuum, plasmids can be viewed as primitive bacteriophages that have not yet acquired those specialised functions necessary for a complex replicative cycle or the production of infectious particles capable of existing outside the host cell. Conversely, bacteriophages can be viewed as plasmids in which a basic replication region has become linked to gene segments that specify the additional biological functions needed for the production of phage particles.

Until recently, it has been generally assumed that the structural evolution of extrachromosomal elements has occurred by mechanisms of "general" or "ordinary" recombination. In *E. coli*, general recombination involves the bacterial *rec*A gene product, and is commonly dependent on physical breakage and reciprocal exchange of DNA sequences in a region of extensive genetic homology[3]. While

this mechanism has undoubtedly played some part in plasmid evolution, experiments carried out during the past several years have shown that the acquisition of certain new segments of genetic material by plasmid and bacteriophage genomes can occur by "illegitimate"[4,5] recombination of DNA sequences that have little or no ancestral relationship[6,7]. Thus, the remarkable structural and genetic diversity of plasmids seems in part to be the consequence of quantal, rather than reciprocal, recombination that involves the joining of termini of separately evolving and structurally defined segments of DNA and the translocation (transposition) of genetic segments from one DNA site to another. Moreover, at least some of the transposable elements involved in the structural evolution of plasmids and other prokaryotic chromosomes can serve also as biological switches capable of turning groups of genes on and off as a consequence of their insertion and excision. Thus, transposable elements seem to have an important role in both the structural organisation and the functional expression of genetic information on DNA.

Segmental composition of large plasmids

Investigations from several laboratories[8-12] have shown that certain large bacterial plasmids can undergo reversible dissociation into separate units in some bacterial species. For example, "cointegrate"[13] antibiotic resistance plasmids can dissociate in *Proteus mirabilis* into separate segments that carry genes for transfer functions (the RTF replicon) or for resistance to antimicrobial agents (the R determinant segment)[8-12]. Each of the two component regions of cointegrate plasmids contains its own replication origin[13]. Since independently formed isolates of an RTF unit derived from the same plasmid seem to be genetically and structurally identical[15,16], dissociation and reassociation (that is, recombination) of cointegrate plasmids must necessarily involve specific DNA loci. Electron microscope heteroduplex studies of the isolated RTF segment of one antibiotic resistance plasmid has shown that it has considerable DNA nucleotide sequence homology with the RTF regions of several other cointegrate plasmids[17]. Moreover, the RTF component of the antibiotic resistance plasmid was found to share much homology with the corresponding segments of the F and ColV-K94 plasmids.

Further heteroduplex mapping of several phenotypically

Table 1 Some properties coded by naturally occurring plasmids

Property	Exemplified by
Fertility—ability to transfer genetic material by conjugation	F, R1, Coll
Production of bacteriocins	CloDF13 (*Enterobacterium cloacae*) ColE1
Antibiotic production	SCP1 plasmid of *Streptomyces coelicolor*
Heavy metal resistance (Cd^{2+}, Hg^{2+})	pI258 (*S. aureus*), R6
Ultraviolet resistance	CollB, R46
Enterotoxin	Ent
Virulence factors, haemolysin K88 antigen	ColV, Hly
Metabolism of camphor, octane, and so on	Cam, Oct (*Pseudomonas*)
Tumorigenicity in plants	TI-plasmid of *Agrobacterium tumefaciens*
Restriction/modification	Production of *Eco*R1 endonuclease and methylase by plasmid of RY13

Plasmids listed are indigenous to *E. coli* unless otherwise indicated.

distinct plasmids has indicated that their regions of homology begin and terminate at very precise boundaries[17]: segments to one side of the boundary show major differences in DNA nucleotide sequences, whereas segments to the other side are preserved largely intact. R-determinant segments of certain antibiotic resistance plasmids isolated in widely spaced parts of the world were found to be preserved almost intact, but no detectable homology was seen with the corresponding segments of the F and ColV-K94 plasmids. Thus, the different phenotypic properties of these large plasmids seem to result in part from the linkage

Fig. 1 Inverted repeats. *a*, Electron photomicrograph of formamide-spread[81] "mini-plasmid" derivative of the pSC105 plasmid[80]. The inverted-repeat units forming the stalk (IR) of the Km-resistance hairpin-loop structure are indicated. *b*, Schematic representation of formation of hairpin-loop structure showing palindromic stem. The DNA nucleotide sequences *ABC* are repeated in inverted orientation on this DNA. Following DNA denaturation and strand separation, hairpin-loop structures can be formed by intrastrand annealing of the complementary nucleotides. The sequence bracketing the base of the stem forms an axis of twofold rotational symmetry.

of separately derived supplemental gene segments to the basic RTF unit. These observations suggest that different combinations of separately evolving DNA segments that have little or no ancestral relationship may be involved in plasmid formation.

Inverted repeats on plasmid DNA

Heteroduplex studies of plasmid DNA sequence relationships by Sharp *et al.*[17,18] also resulted in the discovery of inverted repeats on plasmid DNA. Inverted repeats consist of DNA segments that are duplicated in reverse nucleotide sequence orientation along the genome (Fig. 1). Because of the antiparallel nature of DNA polynucleotide chains, the nucleotide sequences contained within inverted repeats are identical on each of the DNA strands from the 3' to 5' directions; consequently, a structurally defined DNA sequence and its complement exist on each strand of the DNA molecule. During heteroduplex analysis, intrastrand annealing of the primary and repeated complementary sequences results in the formation of hairpin-loop or foldback structures. The complementary sequences are contained in the stalk of such structures, whereas intervening non-duplicated sequences form the loop part. An axis of twofold rotational symmetry bisects the palindromic stem that is formed by intrastrand annealing of the inverted repeat sequences during formamide spreading of DNA for heteroduplex analysis. In at least two instances, antibiotic resistance genes carried by plasmids (that is, the genes specifying resistance to tetracycline and kanamycin-neomycin) were shown to map in the immediate vicinity of inverted repeat structures[17].

Insertion sequence (IS) regions on plasmids

One of the hairpin-loop structures located on the R6 and R6-5 plasmids was found to have another structural feature of special interest. R6-5 is a spontaneously isolated variant of R6; although it does not express the tetracycline (Tc) resistance of the parent plasmid, R6-5 was nevertheless found to contain the hairpin-loop structure associated with the Tc-resistance gene of R6[17]. Electron microscope heteroduplex analysis of the two plasmids indicated that the Tc-sensitive R6-5 plasmid contains all of the DNA sequences present in the Tc-resistant R6 plasmid—plus an additional segment of DNA 1.4 kb in length[17]. Spontaneous excision of the segment from the R6-5 plasmid, which occurs at low frequencies during normal growth of bacteria carrying the plasmid and at higher frequency[19] after transformation[20] of *E. coli* by R6-5 plasmid DNA, leads to regeneration of a plasmid that is phenotypically and structurally identical to the tetracycline-resistant R6 parent. These results indicate that a Tc-resistance gene is present on the R6-5 plasmid, but that it is being inactivated reversibly by insertion of an additional segment of DNA[17].

The inserted DNA segment that turns on and off the expression of tetracycline resistance in the R6-5 plasmid was shown to be a direct duplication of a structurally defined nucleotide sequence that is repeated again in

(Tc-sensitive)

R6 OR S R6-5Tc^R
(Tc-resistant)

Fig. 2 Turn on and turn off of Tc-resistance gene of R6/R6-5 plasmid by excision and insertion of repeated DNA sequence. The nucleotide sequences ABC and $C'B'A'$ form a hairpin-loop structure by intrastrand annealing during spreading of plasmid DNA in the presence of formamide. Insertion of the sequence $A_2B_2C_2$, which is a direct repeat of $A_1B_1C_1$ results in loss of expression of the nearby Tc-resistance gene. Excision of this sequence leads to expression of Tc resistance by the plasmid.

reverse orientation further along the plasmid genome to form the stalk of the hairpin-loop structure near the Tc-resistance gene (Fig. 2). Insertion and excision of this segment of DNA at a site within the loop affects expression of the nearby Tc-resistance gene.

Inactivation of genes as a consequence of insertion of DNA sequences of defined length has been recognised for about a decade. Insertion sequence (IS) elements (for review, see ref. 7), which range in length from 800 to 1,400 base pairs, have been known to become integrated at multiple sites in bacterial and phage genomes and to produce polar mutations[21-25]; insertion of an IS element not only abolishes the function of the gene into which the element is inserted, but it can also affect functioning of genes distal to the insertion site with respect to the promoter of the operon. Moreover, at least one IS element carries a promoter region, and is capable of turning on or off the activity of adjacent genes according to the direction of insertion of the IS segment[25]. The 1.4-kb DNA segment observed to affect expression of tetracycline resistance in the R6/R6-5 plasmid as a consequence of its insertion or

excision seemed to be similar in its characteristics to the IS elements[17].

Subsequent electron microscope heteroduplex studies[26] have shown that the DNA sequence that forms the stalk of the Tc-resistance hairpin-loop structure of the R6 plasmid, and which is also the inserted DNA segment affecting expression of Tc resistance, is one of the previously identified IS regions—IS3. These studies have involved the use of previously characterised[27,28] λ phage mutants carrying the known IS regions; separated strands of phage λ DNA containing IS1, IS2 or IS3 were annealed with R6-5 plasmid DNA, and homology of the IS3 element with the sequence of the Tc-resistance stalk was shown[26].

Parallel investigations by Hu et al.[19] have shown that IS1 and IS2 elements are also present on R6 and R6-5 plasmids, and on the related plasmid R100. IS2 exists as a simple insertion within the RTF unit. Two copies of IS1 exist as direct repeats at the boundaries of the RTF and R-determinants of these plasmids, and by analogy from the data by Sharp et al.[17], exist also at corresponding locations of certain other cointegrate antibiotic resistance plasmids that are homologous with R6 in these regions. Using similar methods, Ptashne and Cohen[26] also demonstrated the presence of directly repeated IS1 insertions at the junction of the RTF and R-determinant units of R6-5.

The discovery of directly repeated copies of the IS1 element at the two junctions of the RTF and R-determinant components of cointegrate antibiotic resistance plasmids provides a possible mechanism for the previously reported reversible dissociation of such plasmids into separate segments[8-11]. The IS1 elements also provide a possible mechanism for amplification of the R-determinant segment and the formation of plasmids consisting of polygenic R-determinant units. As proposed by Hu et al.[29] and by Ptashne and Cohen[26], multiple IS1 copies of and R-determinant units could accumulate on cointegrate R-plasmids by recombination involving the IS1 element. According to this model, the IS1 elements could also mediate dissociation of the component of the plasmid: the number of R-determinant copies included on each of the component replicons would depend on which IS1 regions participate in the recombinational event. Recombination between the most distant pair of R-determinant units as

Cointegrate
R-factor

R-determinant replicon

RTF replicon

RTF component
Fig. 3 Proposed mechanism[26,29] for reversible dissociation of cointegrate R plasmids at sites of IS1 elements. From Ptashne and Cohen (ref. 26). The model depicted provides for the formation of independent RTF and R-determinant replicons (a) and for the production of polygenic R-determinant units. (b). The model is schematic; it has not been determined whether both the RTF and R-determinant units receive IS elements during dissociation of cointegrate R plasmids or whether the two IS1 elements are distributed asymmetrically.

Multiple R-determinant plasmid

shown in Fig. 3 would yield an RTF replicon plus a poly-R-determinant plasmid, whereas recombination between intermediately located IS units would yield a DNA molecule containing both an RTF segment and a varying number of R-determinant copies[26]. Thus, separate RTF and R-determinant replicons[8-11], as well as plasmids containing multiple R-determinant copies[30] could be produced from cointegrate R plasmids by the same recombinational process.

IS elements also seem to be involved in the recombination of F plasmids with chromosal genes to yield F′ plasmids[31-33]. The electron microscope heteroduplex studies of Hu and Davidson and their associates[31-33] have identified three structurally defined DNA segments of F that are hotspots for illegitimate recombination events that do not require bacterial *rec*A gene function. One of these, the εζ sequence, is homologous with IS2 (ref. 29). A second recombinationally active segment on F, the αβ sequence, is indistinguishable from the IS3 element[33]. Formation of an Hfr cell by integration of F into the chromosome can occur by interaction of the plasmid with an IS element inserted in either of two polarities. In 23 of 25 independently derived Hfrs, the point of origin and the direction of transfer of the chromosome by the integrated F plasmid could be predicted by the polarity of the αβ or εζ sequence on the plasmid[32,33]. Taken together, these various data strongly suggest that IS sequences are involved in Hfr formation. These studies[31-33] suggest also that IS elements have a prominent role in the acquisition of chromosomal genes by plasmids and indicate that deletions of F-plasmid DNA can occur during F′-plasmid formation, and that one endpoint of the delegated DNA segment often is coincident with the endpoint of an IS element.

Translocation (transposition) of DNA segments carrying antibiotic resistance genes

In 1964 Dubnau and Stocker[34] reported that antibiotic resistance genes from a plasmid could become associated with the P22 prophage and subsequently attach to the chromosome of *Salmonella typhimurium*. Kondo and Mitsuhashi observed that *E. coli* phage P1 could similarly receive a resistance gene from a plasmid[35]. Later, Mitsuhashi and coworkers[37,38] described the spontaneous integration of R-plasmid genes for choramphenicol (Cm) resistance at various sites of the *E. coli* chromosome, and the subsequent movement of the Cm resistance trait on to another R plasmid or on to bacteriophage P1, which could then transfer the resistance interbacterially. Other observations from the same laboratory suggested that Tc-resistance genes

---

Abbreviated Rules of Nomenclature for transposable elements of DNA*

Definition
Transposable elements are DNA segments which can insert into several sites in a genome.

Classes of element
(1) IS (simple insertion sequences): contain no known genes unrelated to insertion function, generally shorter than 2 kb. Symbols: IS*1*, IS*2*, IS*3* and so on.
(2) Tn (more complex, transposable elements, often containing IS elements): behave formally like IS elements, but contain additional genes unrelated to insertion function, generally larger than 2 kb. Symbols: Tn*1*, Tn*2*, Tn*3* and so on. A different number is assigned to each independent isolate from nature, even if it is apparently identical to some previous isolate. The designations assigned in the accompanying table to some known Tn elements should be used in all publications.
(3) Episomes (complex, self-replicating elements often containing IS and Tn elements).

Organisms and genomes with inserted elements
(1) Organisms. When an inserting element has been introduced into a previously described bacterial strain, the new strain should be given an isolation number. Its genotype can be denoted by the genotype of the parent strain, followed by the name of the element in parentheses.
(2) Genomes. If location is known, specify gene or region in which element is inverted, followed by a number designating the particular insertion mutation, then by double colon and finally by name of inserted element; for example, *gal*T-236 : : IS*1* (IS*1* within gene *gal*T).

Central registry
To avoid duplications of numbers, all new IS and Tn

elements should be checked with a central registry before numerals are assigned to them in publications. A registry for Tn elements will be maintained by Esther Lederberg, Department of Medical Microbiology, Stanford University Medical School, Stanford, California 94305 (USA) as part of the Plasmid Reference Center.

		Designation of Tn elements*		
Element†	Plasmid origin‡	Resistance markers§	References

were also capable of moving from plasmid to plasmid or from plasmid to chromosome[39-41].

In 1968, Anderson *et al.*[42] reported observations suggesting that an Ap-resistance determinant from one plasmid could become associated with another plasmid. Datta *et al.*[43] observed an apparently similar recombinational event that resulted in acquisition by the R64 plasmid of the TEM β-lactamase (Ap resistance) gene originally present on another plasmid, RP4; Richmond and Sykes[44] subsequently reported that the TEM β-lactamase gene derived from the related RP1 plasmid could integrate into the *E. coli* chromosome. Hedges and Jacob[45] isolated a series of plasmid derivatives that had received the Ap-resistance trait from RP4, and found that an increase in plasmid molecular weight accompanied the change to Ap resistance; other plasmids were then able to acquire the TEM β-lactamase resistance from the derivative plasmid. These authors concluded that the structural information for the TEM β-lactamase was carried by a transposable DNA sequence that they termed transposon A (TnA)[45]; Heffon *et al.*[46] subsequently demonstrated that the nucleotide sequences of the TnA segment, which is approximately 3×10^6 daltons in size, are common to naturally occurring plasmids of a variety of compatibility groups that specify the TEM type Ap resistance.

Although these recombinational events apparently involved movement of genetic information from one genome to another, they seemed to involve *rec*A-dependent general recombination. Other experimental evidence, however, has demonstrated that translocation of structurally defined segments of DNA carrying antibiotic resistant genes can occur by terminus-site-specific *rec*A-independent recombination. Some of these events involve known IS elements, which can also move from genome to genome independently of *rec*A function[47]; others seem to be associated with newly observed structurally defined segments of DNA that have been found on plasmids as inverted repeats.

During studies of mobilisation of a non-conjugative plasmid by a conjugally proficient Ap-resistance plasmid[19], a recombinant DNA molecule was isolated, which on further study was shown by electron microscope heteroduplex analysis to have been formed by translocation of a specific DNA segment from one plasmid to another[49]. Translocation of this DNA segment between plasmids did not require the bacterial *rec*A gene product, suggesting that it did not involve ordinary recombination mechanisms. The event was site specific so far as the transposable element itself is concerned (that is, the element could move between plasmids as a discrete structural unit), but the element could become inserted at different sites on the recipient pSC101 plasmid. Heteroduplex analysis showed that all of the sequences present in the translocating Ap-resistance segment were derived from a continuous region of the donor plasmid, and that insertion of the element into the recipient plasmid could occur in either direction[49]. Moreover, a 130-nucleotide long inverted repeat DNA sequence was present at the termini of the 4.5-kb transposable unit.

A schematic representation of these events is shown in Fig. 4. In effect, the plasmid DNA originally located at the ends of the inverted repeat termini of the transposable element is replaced by the recipient plasmid during the translocation event; it is not known, however, whether the transposable unit exists in a physically separate state during the process. In the hairpin-loop structure configuration, (Fig. 4a) the termini of the inverted repeats forming the stem of the Ap-resistance transposable segment are located around an axis of twofold rotational symmetry that marks the site of excision of the element from one plasmid and insertion of the element into another. Alternatively, such molecules may form loop configurations (Fig. 4b) similar to that proposed by Campbell[4] for integration of phage λ into the *E. coli* chromosome, or may form cruciform structures[50]. Although

the actual structural configuration for the transposable segment during the recombinational event is not known, it seems plausible that enzymes capable of recognising the inverted repeat termini of the element may be involved in translocation.

Subsequent experiments[51] have indicated that the structurally defined Ap-resistance element observed to translocate from the pSC50 plasmid on to plasmid pSC101[49] is indistinguishable by electron microscope heteroduplex analysis from the TnA element from R1-19 studied by others[46,52]. Heffron and coworkers[52] have shown that insertion of TnA into a plasmid results in polar mutations similar to those occurring as a consequence of insertion of IS units. Using heteroduplex mapping, these investigators[52] have also demonstrated that the TnA element can insert into multiple sites clustered in a region corresponding to only one-third of the length of the 5.5×10^6 dalton RSF1010 plasmid genome. Similar clustering of sites that have received TnA has been observed on the ColE1 plasmid[53] and on pSC101[51].

Other recent genetic and molecular studies have shown that TnA is one of a number of antibiotic resistance-gene segments of DNA that can undergo *rec*A-independent translocation. In 1972, Chan *et al.*[54] observed that growth of the *S. typhimurium* phage P22 in a bacterial strain carrying the R100 plasmid resulted in formation of an unusual phage varient that could transduce resistance to Tc at a high frequency. The Tc-resistant P22 phage seemed analogous to the antibiotic-resistant P22 phage observed by Dubnau and Stocker[34]; moreover, it did not seem to result from the mechanism normally responsible for the formation of P22 transducing phage, since insertion of Tc resistance into the phage genome did not occur at the site usually associated with attachment of the phage to the *Salmonella* chromosome.

The Tc-resistance DNA segment that had recombined with phage P22 was found to contain a hairpin-loop structure[55] similar to the one identified previously on the R6-5 plasmid[17]. Subsequent studies[56] have demonstrated that this structure, which has inverted repeats of the IS3 element at its termini[26], is capable of translocation from P22 on to many different sites of the *Salmonella* chromosome. Insertion of the transposable element into a structural gene abolishes the function of that gene; moreover, a polar effect on the expression of genes distal to the promoter occurs when the element is inserted into a group of genes that form a single transcription unit[56], as is characteristic of the IS elements[7]. The two inverted repeat copies of IS3 near the Tc-resistance gene seem to be able to undergo translocation concurrently and to carry along the intervening segment of DNA.

Insertion of the Tc-resistance hairpin-loop structure occurs without loss of genetic information from the molecule into which it inserts; most of the mutated bacteria formed as a consequence of insertion can revert to prototrophy[56]. However, excision of the transposible element is usually not precise. Although insertion of the Tc-resistance element into the *Salmonella* chromosome results in a distribution of auxotrophic mutants similar to that obtained by chemical mutagenesis[56], clustering of insertion sites within the histidine operon suggests that insertion may not be entirely random. As in the case of the TnA element, insertion and excision of the Tc-resistance (IS3) segment is independent of the function of the *rec*A gene of the host[56,57].

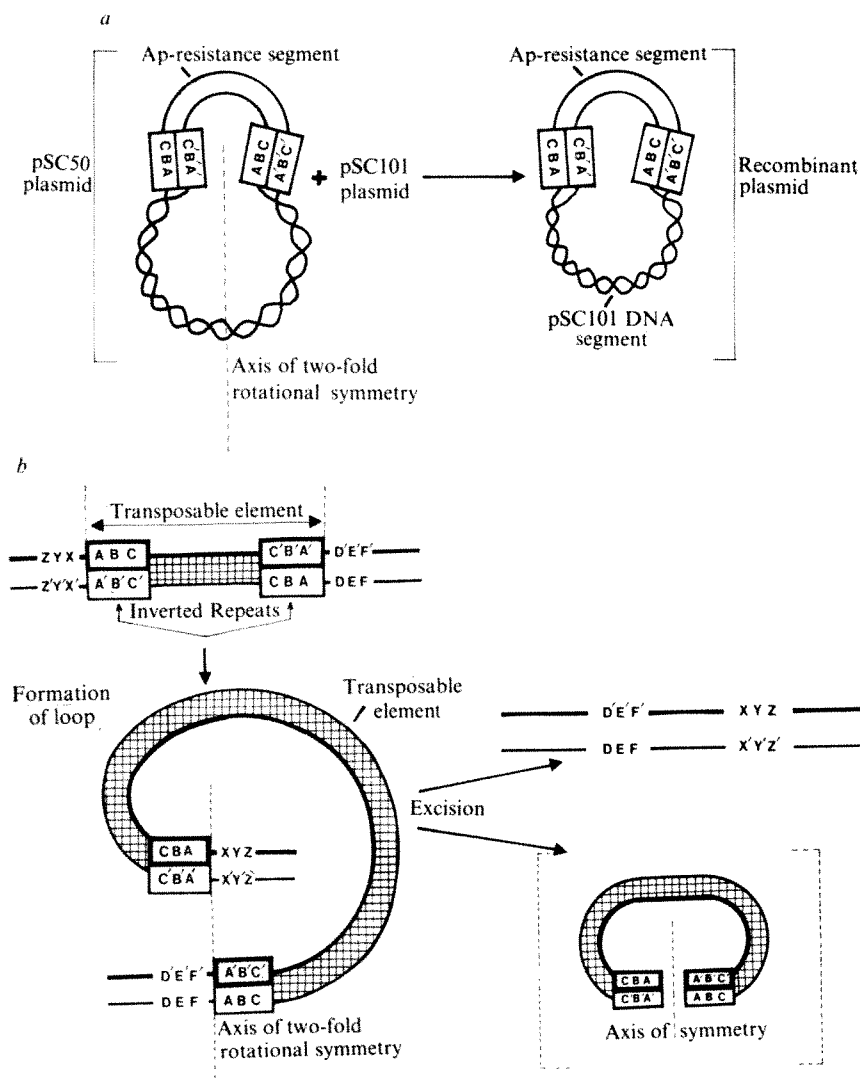
Berg *et al.*[58] have made analogous observations involving a segment of plasmid DNA that carries genes for resistance to the antibiotic kanamycin (Km). This segment contains an inverted repeat hairpin-loop structure similar in appearance to, but different in size from, the structure previously associated with Km resistance on various R plas-


Fig. 4 Translocation of Ap-resistance DNA segment (TnA) from the pSC50 plasmid to pSC101. *a*, Schematic representation showing the Ap-resistance hairpin-loop structure with a 130–140 nucleotide-long inverted repeat stem. As a consequence of translocation, the pSC50 plasmid DNA at the base of the stem is replaced by the pSC101 plasmid (that is, the Ap-resistance segment is translocated from pSC50 to pSC101). Translocation of the hairpin-loop structure involves the ends of the palindromic (stem) sequences that bracket an axis of twofold rotational symmetry. The molecular nature of the DNA product resulting from excision of the Ap-resistance segment from pSC50 is not known. *b*, Possible Campbell model configuration for DNA segment involved in translocation. There is currently no evidence that the same event results in both translocation and restoration of DNA nucleotide sequence continuity at the site into which the Ap-resistance segment has been inserted; although excision with reversion to prototrophy, and translocation are both observed, these outcomes may represent separate events that occur on different DNA molecules, as appears to be the case with bacteriophage Mu[82,83]. The separated Ap-resistance transposable DNA segment is shown in brackets, since its existence as a separate unit has not been demonstrated.

mids[17]. The segment behaves functionally like the Tc-resistance and TnA elements; it can insert at several different sites on phage λ and excision leads to recovery of an intact phage genome. A second Km-resistance DNA segment lacking inverted repeat termini was also observed[38] to be capable of translocation from R plasmids to bacteriophage λ, suggesting that inverted repeats may not be essential for the translocation event or that one of the limbs of the inverted repeat is lost during translocation of this particular element.

Another translocating segment of DNA carrying an antibiotic resistance gene but lacking inverted repeats at its ends has been reported by Gottesman and Rosner[59]. This element had originally been acquired by *E. coli* bacteriophage P1 from the antibiotic resistance plasmid R10 (ref. 35). It was subsequently transferred to phage λ by a process shown to be independent of host *rec* or λ *red* recombination functions; however, possible involvement of P1 recombination functions in the translocation event was not excluded. Very recent investigations (MacHattie and Jackowski, personal communication) indicate that this Cm-resistance translocating segment of DNA contains directly repeated copies of the IS1 element at its termini.

During the studies of Kopecko and Cohen[49], a second transposable element that carries resistance to sulphonamide (Su), streptomycin (Sm) and Ap was observed to move from the pSC50 plasmid to pSC101. Subsequent experiments have shown that this 20.4-kb unit, which has been named TnS, contains the TnA element within it[51]. Inverted repeat segments, 130–140 nucleotides in length, are present at the termini of TnS as well as at the ends of TnA. More-

over, the termini of the TnS element seem to be highly interactive "hotspots" for additional illegitimate recombinational events involving the deletion or insertion of other segments of plasmid DNA[51]. Recently, a segment of DNA carrying genes for resistance to trimethoprim, streptomycin and spectinomycin has also been identified (TnC, ref. 60). Although it is not yet known whether this unit contains either a direct DNA repeat of inverted repeats at its terminal, it seems to be functionally similar to the other transposable antibiotic resistance units described above.

At this time, structurally defined DNA segments coding for resistance to ampicillin, streptomycin–spectinomycin, sulphonamide, chloramphenicol, tetracycline, and trimethoprim have been shown to be capable of translocation from genome to genome, and it seems that the sequential translocation of such segments may be the principal mechanism by which plasmids can accumulate multiple antibiotic resistance determinants. It seems likely that the widespread clinical and veterinary use of antimicrobial drugs has resulted in the biological selection of plasmids that acquire such transposable elements. Possibly, translocation of additional segments of DNA carrying various other plasmid or chromosomal genes remains undetected because comparable selective pressures have not been applied.

While inverted repeats have not been found on all of the antibiotic-resistance transposable DNA studied, they nevertheless seem to be involved prominently in the translocation process. In bracketing an axis of twofold rotational symmetry at the site of recombination of their termini, inverted repeats form a palindromic DNA sequence as noted above. Palindromes have also been observed at the

DNA interaction site for the *ter* enzyme of phage λ[61], at promoter and operator sites associated with λCI (ref. 62) and *E. coli lac*[63] operon repression, and at the sites of action of several restriction and modification enzymes[64,65], suggesting that they may provide highly specific recognition sites for protein–DNA interactions. Observations which show that certain palindrome-site-specific restriction endonucleases are coded by plasmid genes[64] raise the possibility that functionaly analogous plasmid-specified enzymes may have a role in recombinational events involving transposable elements. Moreover, recently obtained data[66] suggest that genetic information required for translocation of at least one of the antibiotic-resistance transposable elements (that is, TnA) is contained within the loop portion of the element itself. It remains to be determined whether other Tn units carry genes that specify products involved in translocation events.

Promotion of other illegitimate recombination events by transposable elements

Reif and Saedler[67] have reported that the IS1 element can promote *rec*A-independent deletion of DNA sequences immediately adjacent to the IS1 terminus. One endpoint of the deletion seems to be the terminus of IS1 itself, whereas the other endpoint is variable. Recent evidence from other laboratories suggests that transposable segments of DNA carrying antibiotic resistance genes can also promote deletion formation, and that such deletions occur at the termini of the inverted repeats. During heteroduplex analysis of the R100 plasmid, Hu *et al.*[29] observed that a transfer-deficient R100 derivative had deleted a DNA segment adjacent to the (IS3) terminus of the Tc-resistance hairpin-loop structure. Foster and Willets[68] subsequently found that following the loss of Tc resistance by R100-1, deletions extending into the adjacent *tra* (transfer) region of the plasmid are observed. Kleckner, Reichardt and Botstein (personal communication) have seen deletion formation also during excision of the Tc-resistance hairpin-loop structure from the *his* region of the *E. coli* chromosome, and D. Berg and B. Allet (personal communication) have observed small deletions in the λ phage chromosome following excision of a Km-resistance transposable element from this DNA segment.

The 130–140-nucleotide long inverted repeats at the termini of TnS also seem to be involved in deletion formation[51,69]. The pSC50 plasmid, which contains both the TnA and TnS translocating elements, is a Km-sensitive derivative of the Km-resistant R1-19 plasmid[49]. Heteroduplex analysis of pSC50 and its parent indicate that the entire segment of DNA located between a terminus of the TnS unit and a copy of IS1 is lost during the formation of pSC50, bringing the termini of TnS and IS1 in juxtaposition[51]. The mechanism by which transposable elements can promote deletion of adjacent DNA sequences is unknown. In at least some instances, however, deletion occurs while the transposable unit is *in situ*, and not at the time of excision or insertion of the element[69].

Conclusions

As a consequence of work carried out in a number of laboratories during the past several years, an understanding of the organisation and structural evolution of bacterial plasmids has begun to emerge. Terminus-site-specific recombination, which in *E. coli* and *Salmonella* is independent of bacterial *rec*A gene function, seems to have an important role; in fact, the addition of structurally-defined DNA segments on to plasmid, phage and bacterial chromosomes, and the excision of specific DNA segments from such chromosomes may represent the principal mechanism by which the organisation of prokaryotic (and perhaps eukaryotic) DNA has evolved. Certainly, this mechanism seems to account significantly for the structural and genetic diversity of plasmids, and to explain at least some types of interaction between extrachromosomal segments of DNA and the host cell chromosome.

Terminus-site-specific recombination also provides a potential mechanism for the exchange of genetic information between diverse biological species found in nature. There has been recent evidence that an Ap-resistance DNA segment found in *H. influenzae* is structurally and genetically similar to the TnA element isolated from *E. coli* plasmids[70]. In addition, translocation of prokaryotic gene segments of eukaryotic DNA sequences cloned in bacteria has been observed (A. C. Y. Chang and S. N. Cohen, unpublished data); it is tempting to speculate that prokaryotic-eukaryotic genetic recombination involving transposable genetic elements may occur under some circumstances in nature.

In addition to having an important role in the structural organisation of genes on prokaryotic genomes, transposable segments of DNA function as controlling elements or "switches" in turning on and off the expression of plasmid and chromosome genetic information. The remarkable dual role of these elements in affecting both the organisation and function of prokaryotic genomes is perhaps best illustrated by the Tc-resistance transposable segment. Inverted repeats of the IS3 element at the ends of this segment can accomplish movement of the intervening Tc-resistance gene between plasmids, chromosome, and phage, and can also lead to deletion of DNA sequences adjacent to the termini; another repeated copy of IS3 controls expression of the Tc-resistance gene contained within the segment of DNA that is translocated. The demonstration that still other insertion sequence elements carry promoter sites[25] for initiation of RNA synthesis provides another potential mechanism by which these units can function as moveable and invertable switches in the evolution of plasmid operons.

Parallels in the effects produced by transposable genetic elements in plasmids, and phenomena observed in eukaryotic systems suggest that similar DNA segments may have a role in the organisation and control of expression of genetic information in higher organisms. The transposable "controlling" elements that regulate phenotypic expression in maize[71-74] are known to be capable of movement to various sites on maize chomosomes; as a consequence of transposition to different locations, they can exert their controlling influence on a variety of genes. As is the case with the inverted repeats identified on transposable antibiotic resistance segments, transposable maize elements seem to promote deletions of various lengths which affect neighbouring genes. Insertion and excision of repeated DNA sequences has been shown recently also to be associated with genetic instability of the *white* locus on the X chromosome of *Drosophila melanogaster*[75,76]. The mutations produced in this locus can be transposed to another linkage group, leaving behind a genetic deletion. Moreover, foldback DNA characteristic of inverted repeats has been found in various eukaryotic chromosomes, and visualisation of this DNA in the electron microscope shows hairpin-loop structures similar to those seen on plasmids[77-79].

Analogies between phenomena observed in eukaryotic systems and the transposable genetic elements and inverted repeats identified on plasmids are presently only speculative; nevertheless, bacterial plasmids may prove to be a highly useful model system for elucidating mechanisms involving the organisation and control of genetic information on the complex chromosomes of higher organisms.

Fission-track dating of zircon separated from two pumice samples from the KBS Tuff in the Koobi Fora Formation, in Area 131, East Rudolf, Kenya, gives an age of 2.44 ± 0.08 Myr for the eruption of the pumice. This result is compatible with the previously published K–Ar and ⁴⁰Ar/³⁹Ar age spectrum estimate of 2.61 ± 0.26 Myr for the KBS Tuff in Area 105, but differs from the more recently published K–Ar date of 1.82 ± 0.04 Myr for the KBS Tuff in Area 131. This study does not support the suggestion that pumice cobbles of different ages occur in the KBS Tuff.

THE Plio-Pleistocene sedimentary sequence in the East Rudolf basin of Northern Kenya, has been the site of many important hominid[1], archaeological[2] and palaeontological finds[3]. Intercalated with the sequence of lacustrine, deltaic and fluviatile sediments are a series of prominent felsic volcanic tuffs. These volcanic units have been used to establish a time framework for the rocks of the East Rudolf Basin[4]. K–Ar and ⁴⁰Ar/³⁹Ar dating techniques have been applied to >100 rock and mineral samples from East Rudolf, but interpretation of the dates determined by these methods has not been straightforward. Geological[5] and

analytical[8,9] factors have been postulated to explain the scatter of K–Ar and [40]Ar/[39]Ar apparent ages obtained from volcanic sanidine–anorthoclase crystals separated from pumice cobbles in the tuffs.

The KBS Tuff, lying within the Lower Member of the Koobi Fora formation, has attracted considerable interest amongst palaeontologists and anthropologists because it contains an important stone artefact site[2] and overlies the bed which contained the hominid cranium KNM ER 1470 (ref. 1). In 1970, Fitch and Miller[6] published a K–Ar and [40]Ar/[39]Ar age spectrum analysis of fresh sanidine crystals separated from pumice cobbles present in the KBS Tuff in Area 105, giving a preliminary date of 2.61 ± 0.26 Myr for the KBS Tuff horizon. Recomputation of this data using improved [40]Ar/[39]Ar techniques, together with additional [40]Ar/[39]Ar dating studies leads Fitch *et al.*[7] to the conclusion that a more precise minimum age for the KBS Tuff is 2.42 ± 0.01 Myr.

Curtis has described the original 2.61 ± 0.26 Myr date for the KBS Tuff as being much questioned in private anthropological and palaeontological circles[8]. These doubts led Curtis *et al.* to undertake an independent check, using conventional K–Ar dating techniques on sanidine and glass separated from KBS pumice[9]. The tuff known as KBS in Areas 10 and 105 is distinguished by Curtis *et al.*[9] from the tuff known as KBS in Area 131 on the basis of K–Ar total fusion dates obtained from these areas: 10 and 105 give a mean date of 1.60 ± 0.05 Myr, 131 giving a mean date of 1.82 ± 0.04 Myr. The 2.61 ± 0.26-Myr date of Fitch and Miller[6] is explained by Curtis *et al.*[9] as possibly resulting from the presence of older pumice blocks in the KBS Tuff. Curtis underlines the desirability of checking radiometric dates by the use of two different methods, and he cites the fission-track dating work on the East Rudolf Tuffs being undertaken at Birkbeck College[8]. Because of the great interest in the KBS Tuff horizon and the apparent conflict between the K–Ar and [40]Ar/[39]Ar results, we present here the first dates obtained using the independent technique of fission-track dating on zircon from pumice cobbles collected at one locality in the KBS Tuff. This work represents part of a larger fission-track dating study being made on each of the tuff horizons in the East Rudolf Basin. Full publication of the fission-track results will be made on completion of the project. The theory and techniques of fission-track dating have been comprehensively described[10], as has the specific use of zircon in dating young volcanic ash beds[11].

Method

The two pumice samples used in this study, FMA 517 and ER 74/131 came from within 5 m of each other, from the KBS Tuff in Area 131. Sample FMA 517 was collected in 1974 by I. C. Findlater, F. J. Fitch and A. J. Hurford, and was used in a further [40]Ar/[39]Ar dating study undertaken at Cambridge[7]. FMA 517 consists of several well rounded

pumice lumps collected within 4 m of each other. The pumice is rich in euhedral feldspar phenocrysts and contains glass showing partial replacement by calcite. Sample ER 74/131 was collected by T. E. Cerling and was used in the K–Ar dating study undertaken at Berkeley[9]. This single pumice lump contained dark, isotropic glass and abundant euhedral feldspar crystals. The pumice samples were crushed and carefully digested in a mixture of concentrated HF and concentrated H_2SO_4 for 7 d (ref. 16). This digestion process dissolved most of the rock leaving a concentrate of zircon which was further purified by conventional mineral separation techniques. The zircons consist of two distinct varieties: ~95% are colourless, water-clear unzoned euhedral crystals, 200–50 μm in length and often containing many randomly orientated acicular inclusions together with irregularly shaped fluid inclusions. These crystals all have very low spontaneous fission-track densities. From the perfect, euhedral nature of these zircons, they must be regarded as juvenile crystals, primary to the eruption of the enclosing pumice. Approximately 5% of the zircons are variable in form and much darker in colour. They are light brown to red, often strongly zoned and have a very rounded form, with no discernible crystal faces or inclusions. Since these crystals all have high spontaneous fission-track densities, they appear to be old, detrital zircons and therefore they are excluded from the determinations shown in Table 1.

Four determinations were carried out on sample FMA 517, three at Birkbeck College, London, and one at the US Geological Survey, Denver, Colorado. One determination was carried out on sample ER 74/131 at Birkbeck College. The techniques used for dating the zircons in both laboratories are essentially those described by Naeser[12], except that the tracks were etched in a molten eutectic of KOH and NaOH at 220 °C for between 60 and 100 h (ref. 13). The external detector method was used, [238]U spontaneous fission tracks being counted in the zircon and [235]U induced fission tracks counted in a calibrated external mica detector. Neutron irradiations were carefully monitored by counting tracks from the NBS standard glass SRM 612, which had been calibrated previously against the NBS dosimeter glass SRM 962 and a large number of cobalt wire activation measurements. Using these techniques and a value for the [238]U spontaneous fission decay constant, λ_f of 6.85×10^{-17} yr^{-1} (ref. 10) we have obtained ages on standard zircons which agree very closely with their independently known ages[13]. We believe, therefore, that this value of λ_f is that which is most appropriate to fission-track dating. Fission-track ages have been calculated using the equation of Fleischer *et al.*[14]. The results of the five determinations are shown in Table 1.

In addition to the dates shown in Table 1, counting of three of the detrital grains from FMA 517 by one of us (AG) gave dates of 303 ± 32, 380 ± 62 and 293 ± 52 Myr,

Table 1 Fission-track dating results of two pumice samples from the KBS Tuff, East Rudolf

Sample no. and Determination no.	No. of zircons	Spontaneous tracks No. counted	ρ_s (cm^{-2})	Induced tracks No. counted	ρ_i (cm^{-2})	Neutron fluence φ (n cm^{-2})	Age (±1σ)(Myr)
FMA 517 (1) AJH	10	47	7.05×10^4	1,428	4.28×10^6	2.52×10^{15}	2.55 ± 0.38
FMA 517 (2) AJH	10	56	7.87×10^4	1,129	3.18×10^6	1.59×10^{15}	2.42 ± 0.32
FMA 517 (3) AJWG	6	36	7.09×10^4	802	3.32×10^6	1.81×10^{15}	2.37 ± 0.41
FMA 517 (4) CWN	12	22	9.55×10^4	311	2.70×10^6	1.11×10^{15}	2.41 ± 0.53
						Mean date of FMA 517	2.44 ± 0.08
ER 74/131 (1) AJH	8	21	1.34×10^5	411	5.26×10^6	1.55×10^{15}	2.43 ± 0.55

suggesting an age for the detrital component of about 325 Myr. These results confirm that the pumice blocks had been contaminated by older zircons, possibly during eruption, or by the penetration of detrital grains into the pumice vesicles, during transportation or on deposition. During the fission-track dating procedure this inherited component can be identified easily by the morphology and high track density of these particular zircons. For this reason, it is quite certain that none of these older crystals has been included in the dating of the primary zircons.

The mean of the four determinations on FMA 517 is 2.44 ± 0.08 Myr and this cannot be distinguished from the single determination of 2.43 ± 0.55 Myr for ER 74/131. These dating results provide strong evidence that the primary zircon component in pumice samples from the KBS Tuff in Area 131 has an age close to 2.44 Myr. This may be taken also as the age of eruption and deposition of the KBS Tuff, provided the zircon dates have not been reset by some later event and provided the dated pumices are of the same age as the surrounding tuffaceous matrix. Extrapolation of laboratory annealing studies[14,16] indicates that fission tracks in zircon should be stable over a period of 3 Myr at temperatures up to at least 300 °C. It is highly unlikely, therefore, that the zircon fission-track dates have been reset by any later thermal events.

Curtis *et al.*[9] report that sample ER 74/131 has a K–Ar apparent age of 1.82 ± 0.04 Myr whereas Fitch *et al.*[7] interpret a ⁴⁰Ar/³⁹Ar age spectrum on FMA 517 as indicating an original date of 2.47 ± 0.60 Myr, overprinted at 1.91 ± 0.03 Myr. To explain such variation in K–Ar and ⁴⁰Ar/³⁹Ar estimates of the age of the KBS Tuff, it has been suggested that pumice of more than one age may be present in this horizon[9]. Our limited data do not support this conclusion. The pumice samples ER 74/131 and FMA 517 dated in this study give virtually identical fission-track results of ~2.44 Myr, suggesting that these two samples of pumice cobbles are of the same age.

Conclusion

The mean zircon fission-track date of 2.44 ± 0.08 Myr provides a close estimate of the age of the eruption of the pumice samples collected from the KBS Tuff in Area 131. These fission-track results are also consistent with the palaeomagnetic stratigraphy established by Brock and Isaac[17] on the basis of the original 2.61-Myr date[6] for the KBS Tuff. From consideration of the data currently available, the date of 2.44 ± 0.08 Myr probably represents a close estimate of the age of eruption and deposition of the KBS Tuff.

P. J. Hooker & J. A. Miller
Department of Geodesy and Geophysics, University of Cambridge, Madingley Rise, Madingley Road, Cambridge CB3 0EZ, UK

⁴⁰Ar/³⁹Ar and conventional K–Ar age determinations on volcanic sanidine–anorthoclase crystal concentrates from pumice lumps contained within the KBS Tuff in the Koobi Fora Formation at East Rudolf indicate an apparent age near 2.42 Myr. Recomputation of data obtained in 1969 from this tuff suggests a more accurate apparent isochron age of 2.42 ± 0.01 Myr for the feldspar, coincident with total fusion conventional K–Ar and ⁴⁰Ar/³⁹Ar dates of ~2.4 Myr from the same sample. Age spectra and total fusion dates obtained from other samples of the KBS Tuff confirm this conclusion. Thus, apparent ages of < 2.4 Myr derived from some of our samples and conventional total fusion K–Ar apparent ages in the range 1.6–1.8 Myr obtained from the KBS Tuff by other workers are regarded as discrepant, and may have been obtained from samples affected by argon loss. This latter conclusion is compatible with our ₚsector interpretation of the age spectrum analyses of KBS pumice feldspars. Argument for there being more than one tuff complex or an admixture of older pumice in the KBS Tuff is not supported by our work.

CONTROVERSY over the age of the KBS Tuff in the Koobi Fora Formation of the East Rudolf sedimentary basin of northern Kenya has arisen very largely from apparently conflicting evidence derived from the different approaches to the measurement of geological time. Exploration of the basin in 1968 and 1969 led to the identification of the KBS Tuff and an overlying unconformity[1–3]. Samples were collected then from an outcrop of this tuff in Area 105, East Rudolf and forwarded to Cambridge for dating[4]. It is now known that the KBS Tuff was deposited by a major river entering Lake Turkana (formerly Lake Rudolf) from the north-east, and numerous lines of evidence suggest that the time between eruption and deposition was negligible[5–7]. Exploratory conventional K–Ar dating in 1969 revealed the presence of detrital impurities in the vitric tuff sample that made its apparent ages discrepantly high (> 200 Myr). It was immediately clear that unless contamination-free fractions could be found the East Rudolf tuffs would not produce satisfactory samples for geochronometric analysis. Attention was concentrated, therefore, on pumice samples and on a large clean sample of volcanic feldspar extracted from pumice in the field. These

samples were carefully prepared in the laboratory to avoid contamination and analysed by the conventional K–Ar total fusion method and by the then new ^{40}Ar/^{39}Ar total fusion and age spectrum methods[8-11]. Developments in the analytical techniques of ^{40}Ar/^{39}Ar dating since then[12-14] enable recomputation of the results obtained, using, in
Fig. 1 Isochron diagram for the plateau sector of age spectrum No. 1 (Fig. 1 of ref. 4) of subsample Leakey I/B2 (d). Apparent age of isochron is 2.42 ± 0.01 Myr; intercept value on ^{40}Ar/^{36}Ar axis is 294.

addition, a more accurate value for the constant of proportionality (J) used in the 1969 experiments. These revised data are listed in Table 1 along with the total fusion K–Ar ages obtained from other subsamples of sample Leakey I for comparison.

Detrital contamination

In all K–Ar dating, some argon loss must be suspected in total fusion results until disproved. In addition, small contamination errors may be present in our total rock pumice samples even though they were selected from the cores of well-washed larger lumps. The concentrates of volcanic feldspar sent to the UK in 1969 consisted of a small number of large (up to 7 mm average diameter) euhedral sanidine–anorthoclase crystals and a greater quantity of small (1.0–5.0 mm average diameter) euhedral feldspar crystals and aggregates containing aegerine–augite and/or iron ore as well as feldspar. A number of different (unequal) subsamples were selected from this feldspar concentrate for dating, so that the presence of any 'detrital' contaminent would be revealed by variation in their apparent ages. The largest, most euhedral feldspars, were hand-picked for ^{40}Ar/^{39}Ar age spectrum analysis No. 1.

Five further subsamples, each consisting of smaller feldspars free from pyroxene and iron ore, were prepared and three of these were subsequently used for total fusion ^{40}Ar/^{39}Ar and total fusion conventional K–Ar dating.

The virtual coincidence of the apparent ages obtained from determinations made by different methods on four different subsamples of the feldspar concentrate Leakey I/B2 suggests that this concentrate does not suffer from significant detrital contamination. Error attributable to variable but very minor argon loss remains, however, and this is confirmed by the shape of the age spectrum. Thus, the best minimum age for the KBS Tuff currently available from this sample is 2.42 ± 0.01 Myr (revised apparent isochron age of plateau sector of age spectrum No. 1).

Argon loss

During the period 1971–73 further samples were collected from the KBS Tuff at various localities in the East Rudolf basin by I. C. Findlater. Each of the samples was a cleaned and acid-washed feldspar crystal concentrate extracted from
Fig. 2 Correlation diagram plot of total fusion ^{40}Ar/^{39}Ar age determination data obtained from feldspar concentrates separated from KBS pumice, East Rudolf, Kenya[15]. ^{39}Ar/^{36}Ar values are normalised to a constant J. See text. The straight line is the 2.4-Myr isochron envelope.

pumice by hand picking only the most obviously juvenile crystals from sawn slabs of pumice beneath a binocular microscope. The results of twelve total fusion and six age spectrum ^{40}Ar/^{39}Ar age determinations on these KBS feldspar samples were briefly summarised at a symposium held in Nairobi in 1973[15]. The apparent ages obtained from samples from Areas 10, 130, 131 and 105 show a scatter between 0.5 and 2.4 Myr. The available ^{40}Ar/^{39}Ar total fusion data from the KBS Tuff pumice feldspars is plotted as a correlation diagram in Fig. 2.

Because of the care taken in their preparation, and by analogy with the data obtained from the various Leakey

†Revision of previously published data.
Fig. 3 $^{40}Ar/^{39}Ar$ age spectrum of KBS pumice feldspar sample FMA 274, Area 10, East Rudolf. The two plateau sectors of the spectrum have apparent ages of 1.94 Myr and 2.46 Myr respectively.

1/B2 feldspar crystal subsamples, the results are very unlikely to be marred by contamination. The scatter of apparent ages obtained must be explained, therefore, by the loss of varying amounts of Ar from the feldspars. If it is accepted that contamination is not significant in these samples, then a minimum age of 2.4 Myr for the KBS Tuff is indicated assuming an intercept value of 296 on the $^{40}Ar/^{36}Ar$ axis.

High temperature volcanic sanidine–anorthoclases are highly unstable minerals with aluminium and alkali atoms at random sites in the lattice. During subsequent changes of state towards more ordered low temperature forms of greater stability, significant losses of Ar may result. If these order–disorder processes are accentuated at any time by periods of thermal or hydrothermal activity, then related Ar loss may be identifiable in the K–Ar age patterns of samples of these feldspars. We believe that the complexities of some of the age spectra we have obtained from KBS feldspar samples can thus be explained and may even be resolvable[5,15].

Age spectra

Complex age spectra from four samples of KBS pumice feldspar from Area 130, East Rudolf (FMA 201, 206, 225, 227) provide strong evidence of K–Ar age discrepancy[16,17], which we attribute to argon loss. Two major age components can be recognised in the four age spectra: one apparently at 1.75–1.8 Myr and another apparently at ~ 1.07 Myr. When the data defining these sectors are plotted on correlation diagrams, regression line intercept values considerably less than 296 are obtained on the $^{40}Ar/^{36}Ar$ axis, thus giving further support to the overprinting hypothesis[17,18]. Similarly it can be suggested that at least two age sectors, ~ 1.9 Myr and 1.02 Myr are present in the complex age spectrum obtained from a further sample (FMA 294) of KBS pumice feldspar from Area 105. Such suggestions are not, however, conclusive.

An age spectrum obtained from a sample of clean, detritus-free KBS pumice feldspar (FMA 274) from Area 10, East Rudolf is, however, particularly instructive. Two aspects of the data from this sample are illustrated in Figs 3 and 4. The age spectrum (Fig. 3) is seen to have two short plateau segments apparently ~1.94 Myr and 2.46 Myr respectively. This type of double plateau age spectrum might be interpreted as suggesting either partial overprinting at 1.94 Myr of feldspar originally 2.46 Myr old, or the presence of contamination, but when the data are examined on a correlation diagram (Fig. 4) it is seen that another interpretation is possible: two slightly different feldspar components of unlike initial argon composition

but of identical apparent age are present, one having a regression age of 2.39±0.01 Myr (intercept value, 297) the other 2.42±0.03 Myr (intercept value, 272). The difference in intercept value between these two age components could result from one being accessory feldspar outgassed during the eruptive event of 2.4 Myr ago, whereas the other is of entirely juvenile origin. We feel that the data from sample FMA 274 provide strong additional evidence for a 2.4-Myr age for the KBS Tuff. Thus, our dating of samples of KBS pumice feldspar from other localities at East Rudolf seems to confirm the minimum age of 2.42 Myr derived from sample Leakey I and to suggest that discrepancies from Ar loss, particularly ~ 1.75–1.9 Myr and 1.05 Myr may be important in many KBS samples (see also the data from sample FMA 517, discussed below).

Opposition to our dating

Over the past five years, opposition to the acceptance of a ~2.5-Myr age for the KBS Tuff has come from three sources: first, archaeologists and palaeoanthropologists disturbed by the consequent antiquity of hominid fossils and stone tools found close to or associated with the KBS Tuff, second, palaeontologists reporting apparent misfits between the faunal sequences at East Rudolf and elsewhere, and third, from a small programme of conventional total fusion K–Ar age determinations on East Rudolf pumice samples undertaken at Berkeley[19-21]. We believe that the attempts at biostratigraphic and archaeological correlation so far made have been premature and confidently expect the problems raised by these workers[22-24] to disappear as more accurate faunal lists and local time scales are produced. The inconsistencies that have arisen from the application of different K–Ar dating techniques to samples of the same tuff do, however, require further comment now.

At present, the KBS Tuff is the only tuff in the East Rudolf succession whose apparent age is controversial. For example, from an extensive combination of total fusion and age spectrum $^{40}Ar/^{39}Ar$ age determinations, we estimate the best age of the Chari/Karari Tuff level at East Rudolf to be 1.32±0.05 Myr (ref. 6). This particular age was an isochron determination derived from a pumice sanidine sample which we would regard as ideal K–Ar dating material, totally free from either initial argon or argon loss discrepancies. It is instructive that identical ages have been obtained for the Chari and Karari Tuffs by conventional K–Ar dating at Berkeley (G. H. Curtis, personal communication) and similarly from Omo Tuff KNW2,

Fig. 4 Correlation diagram obtained from age spectrum analysis of KBS pumice feldspar sample FMA 274. Two distinct components seem to be present with regression line ages of a, 2.39 ± 0.01 Myr (intercept value: 297) and b, 2.42 ± 0.03 Myr (intercept value 272).
Fig. 5 $^{40}Ar/^{39}Ar$ age spectrum of KBS pumice feldspar sample FMA 517, area 131, East Rudolf (same locality as Berkeley samples ER74–131). The age spectrum has a 'peak' age of 2.47 ± 0.6 Myr then declines through a 'flat' at ~ 1.8 Myr.

which is thought by Brown[25] to be the lateral equivalent of the Chari/Karari level in southern Ethiopia. Thus, it is clear that the inconsistencies between conventional K–Ar and $^{40}Ar/^{39}Ar$ dating of the KBS Tuff most likely arise from some inherent characteristics of the samples rather than differences in the dating methods used.

Conventional K–Ar dates of feldspars from the KBS Tuff quoted by Curtis *et al.*[21] scatter between 6.90 ± 0.05 Myr and 1.50 ± 0.02 Myr. Clearly, detrital contamination was present in some of the Berkeley dating samples prepared by heavy liquid concentration alone, but, the subsequent recognition of a number of yellow; rounded, and thus probably detrital, grains in the unused portion of a dated sample does not necessarily prove that any detrital grains were present in the small aliquot of the sample actually used for the argon analysis. Thus, it is still possible that some of the apparent ages between 1.85 Myr and 2.4 Myr rejected by Curtis *et al.* may result, at least in part, from the presence of a non-detrital 2.4-Myr-old component.

Comparison

Data obtained at Cambridge from the $^{40}Ar/^{39}Ar$ age spectrum analysis of KBS pumice feldspar sample FMA 517, collected from the same locality in Area 131, East Rudolf as Berkeley samples ER74–131 are presented in Figs 5 and 6. The mean of six conventional total fusion K–Ar ages on undoubtedly detritus-free pumice feldspar and glass fractions

Fig. 6 Correlation diagram obtained from age spectrum analysis of KBS pumice feldspar sample FMA 517. Two age components seem to be present. The age of the older (*a*) cannot be defined more closely than the rather imprecise 'peak' age of 2.47 ± 0.6 Myr., but the younger (*b*) has a regression age of 1.91 ± 0.03 Myr (intercept value, 285).
of the samples ER74-131 carried out at Berkeley was 1.82 ± 0.04 Myr. This age is regarded by Curtis *et al.* as a good estimate for the date of eruption of the KBS Tuff in Area 131, whereas, from our experience we would interpret it as being the date of total argon loss, affecting glass and feldspar crystals alike. Unfortunately, the results of the analysis of sample FMA 517 are not absolutely conclusive. The age spectrum (Fig. 5) contains a 'peak' apparent age of 2.47 ± 0.6 Myr, but at later steps the apparent age curve declines to a 'flat' apparently close to 1.8 Myr. On the correlation diagram (Fig. 6) the data fall into two groups : the younger of the two age components has an apparent age of 1.91 ± 0.03 Myr (with an intercept value of 285, suggestive of overprinting). Because insufficient data are available, the apparent age of the older component cannot be estimated with any more precision than was given to it by the peak on the age spectrum. The major feldspar component in sample FMA 517 clearly has an apparent age of 1.91 ± 0.03 Myr.

The six total fusion K–Ar ages obtained at Berkeley, the apparent age of the lower sector of the age spectrum, and a total fusion $^{40}Ar/^{39}Ar$ apparent age of 1.72 ± 0.11 Myr obtained from another subsample of pumice feldspar FMA 517 at Cambridge, must be regarded as less precise estimates of the age of this component, because they undoubtedly contain an uncorrected initial argon discrepancy and, in the case of the total fusion dates, a variable contribution from the older feldspar component.

Conclusion

By analogy with our other work on the KBS Tuff, we believe that in Area 131 the older feldspar age component represents the true age of crystallisation and the dominant younger component defines no more than the age of a widespread overprinting event, but there is nothing in the available K–Ar and $^{40}Ar/^{39}Ar$ data that makes this interpretation unique.

In these circumstances we must await confirmation from further work on samples from Area 131, especially work using methods of estimating geological time which are independent of the K–Ar dating technique. At East Rudolf, palaeomagnetic reversal chronology[26,27], and fission track dating[28,29] are the methods most likely to resolve this controversy.

One further conclusion appears inescapable: as multiple age component systems and age components with apparent initial Ar isotope ratios unlike the modern atmosphere ratio are present amongst the pumice feldspar samples from the KBS Tuff, variation in the total fusion K–Ar or $^{40}Ar/^{39}Ar$ apparent ages of samples from different localities is to be expected. Thus the conventional total fusion K–Ar dating evidence at present available cannot be used either to confirm or to deny the presence of more than one tuff or pumice population at the KBS level. It is our opinion, however, that the balance of evidence from a combination of the currently available K–Ar and $^{40}Ar/^{39}Ar$ work strongly suggests that only one tuff complex is present, it was deposited within a short interval in all areas, it contains one dominant pumice generation and this pumice is 2.42 Myr old.

A chemically synthesised duplex DNA fragment containing the sequence of the lac *operator was cloned in* E. coli *using the vehicle pMB9. Clones containing lac-pMB9 hybrid DNA produced β-galactosidase constitutively and the hybrid DNA bound the* lac *repressor specifically.*

THE nucleotide sequence of the *lac* operator has been determined by Gilbert and Maxam[1]. We have synthesised chemically an oligonucleotide duplex, 21 nucleotides long and containing the sequence of the *lac* operator, and have shown that it binds the *lac* repressor specifically[2]. Here, we report the enzymatic joining of a synthetic *lac* operator fragment with protuding 5' pA–A–T–T sequences (Fig. 1) directly to *Eco*RI endonuclease-cut pMB9 DNA[3]. After transformation, clones containing hybrid *lac*-pMB9 DNA expressed the biological activity *in vivo* of the chemically synthesised *lac* operator by producing β-galactosidase constitutively. Furthermore, the *lac* operator DNA reisolated from the hybrid DNA by cleavage with the *Eco*RI restriction enzyme[4] showed specific and strong binding to the *lac* repressor. The reisolated *lac* operator DNA with protruding 5' pA–A–T–T sequences can be joined by T4 polynucleotide ligase to produce multi-operator fragments of up to 18 copies of the *lac* operator in tandem. Some of the multiple operators were ligated with *Eco*RI endonuclease-cut pMB9 DNA, and hybrid DNA with two copies of the *lac* operator was isolated.

In addition to the specific method reported here, a more general approach for inserting any even-ended DNA fragment into plasmid DNA has been developed. In this approach[19], a chemically synthesised decanucleotide duplex containing *Bam*I restriction endonuclease[5] recognition sequence is joined to an even-ended *lac* operator DNA duplex[2] by T4 polynucleotide ligase (ref.6). Digestion of the ligated product with the *Bam*I endonuclease generated the protruding 5' pG–A–T–C sequence. This molecule was then joined to the *Bam*I endonuclease-cut pMB9 DNA. Details of these results will be reported elsewhere[19].

Characterisation and analysis of hybrid plasmids

Results in Table 1 show that clones 50, 67 and 162 produced large amounts of β-galactosidase and that the DNA isolated from these clones bound the *lac* repressor extensively. The DNA from pMB9 plasmid and the three clones which produced very low levels of β-galactosidase all showed essentially no binding. The DNA from clones 67 and 162 was further examined by digesting the samples with *Eco*RI enzyme and carrying out electrophoresis using a 3%:15% polyacrylamide step gel. To detect *lac* operator-size small DNA fragments, the digest was labelled by repair synthesis[7] at the cohesive ends with DNA polymerase I and α-^{32}P-dATP. Figure 2 shows that the plasmid-size linear DNA band is clearly present in all cases. However, digests of the DNA from clones 67 and 162 also show an operator-size DNA fragment in the lower portion of the gel. The ratio of counts in the operator fragment to the plasmid DNA was nearly 1:1 for clones 67 and 162, indicating that only one copy of the *lac* operator had been inserted per plasmid. This was explored further by partially digesting the hybrid plasmids with the *Eco*RI enzyme followed by labelling, using repair synthesis (Fig. 3). Even though partial digestion products of the plasmid DNA can be seen, only one operator-size species is present in all cases. If multiple operator species were present, one would expect to see one or more bands above that of the *lac* operator DNA in the 15% gel. The small fragment was shown to be *lac* operator DNA on elution from the gels and testing its binding to the *lac* repressor. The results are shown in Table 1b. Each fragment tested gave excellent binding with the *lac* repressor. Since only the centre 21 nucleotides out of the completely repaired 31-nucleotide-long duplex had the correct sequence for the natural *lac* operator, the nucleotide sequences beyond the central 21-nucleotide sequence were not needed for the recognition by the *lac* repressor[2]. In fact, wrong sequence beyond the central 21 nucleotides did not seem to interfere with the repressor binding.

The structure of the operator fragments was confirmed by determining their nucleotide sequence. Operator fragment was labelled at the 3'-ends with ^{32}pA^{32}pA by partially repairing the protruding 5'pA–A–T–T ends using DNA polymerase I and α-^{32}P-dATP. The resulting 29-nucleotide-long strands were

separated by gel electrophoresis (Fig. 4). The sequence of each strand was then determined using a partial pancreatic DNase digestion followed by two-dimensional electrophoresis–homo-chromatography[8,9]. Figure 5a and b shows the sequences 5′ . . . A–G–C–G–G–A–T–A–A–C–A–A–T–T–G–[32]pA[32]pA

and 5′ . . . T–T–A–T–C–C–G–C–T–C–A–C–A–A–T–T–G- • [32]pA[32]pA, respectively. Written in the duplex form, these sequences overlap by nine nucleotides which confirm the expected sequence of the two 27-nucleotide-long single strands as shown in Fig. 1b.
Fig. 1 Joining of the chemically synthesised *lac* operator duplex with protruding 5′ A–A–T–T sequence with *Eco*RI endonuclease-cut pMB9 DNA. The three oligonucleotides used to make the duplex fragment (structure *a*) were synthesised by the modified phosphotriester method[11–14] and are indicated by the dotted lines. Enzymatic joining of the oligonucleotides was carried out with T4 polynucleotide ligase[2] and the duplex fragment was separated from the single-stranded oligonucleotides by elution from a Sephadex G-75 column with 0.1 M NaCl. The duplex (underlined with solid line) was synthesised so that the recognition sequence of the *Eco*RI restriction endonuclease was present at both ends. Before joining the fragment with pMB9 DNA it was necessary to incorporate one dGMP residue into each of the single-stranded ends to produce structure *b*. This *lac* operator duplex with protruding 5′ A–A–T–T sequence (1 pmol) was joined to pMB9 DNA (0.3 pmol) which had been made linear by digestion with *Eco*RI endonuclease. Ligation reaction was at 12.5 °C for 20 h. The resulting hybrid *lac*–pMB9 DNA was used to transform 3 × 10⁷ competent *E. coli* HB129 cells[3] as follows: The DNA and recipient cells were mixed together and incubated at 0 °C for 30 min. The temperature of the mixture was raised to 42 °C for 2 min and then chilled to facilitate uptake of the DNA by the cells. Nine volumes of prewarmed L-broth were added and the cells allowed to recover at 37 °C for 2 h. One volume of L-broth supplemented with 10 μg ml⁻¹ of tetracycline was then added. After an additional 30 min at 37 °C the tetracycline concentration was brought up to a final level of 20 μg ml⁻¹. This cell suspension was used to inoculate 100 ml of M9 medium for the isolation of a larger amount of plasmid DNA[15]. This plasmid DNA (30 μg) which contained some hybrid *lac*–pMB9 DNA was enriched for *lac* sequences by binding it to the *lac* repressor (4.5 μg) on a Millipore filter, and eluting it with 1 ml of 1 mM isopropyl thiogalactoside (IPTG). This DNA (6% of the input), enriched for *lac* sequences, was used for a subsequent transformation on nutrient agar plates containing 20 μg ml⁻¹ of tetracycline. The frequency of transformation was 6.4 × 10⁻⁴ transformants per μg per DNA per viable cell whereas in the same conditions native pMB9 gave a frequency of 1.8 × 10⁻².

Table 1 *Lac* repressor binding

a Clone	β-Galactosidase level	Binding (%)	b Clone	Binding (%)
44	Low	0	67	28
50	High	70	162	31
67	High	72		
84	Low	4		
114	Low	3		
162	High	60		
pMB9	Low	0		

Lac repressor binding of hybrid *lac*–pMB9 plasmids and isolated operator fragments. All *lac* repressor binding assays were performed in 100 μl of binding buffer[17] containing 1.3 μg of *Hin*dII + III digested λ*plac*5 DNA (40 fmol *lac* operator), radioactive DNA sample (1–4 fmol) and 200 fmol *lac* repressor[2]. The mixture was left at room temperature for 30 min. Triplicate samples of 30 μl each were filtered through Millipore HAWP 0.45-μm filters and then washed three times with 200 μl of a washing buffer[17]. 1 ml of 1 mM IPTG was then passed through the filter and the eluate collected. Percentage binding is defined as the fraction of total input counts eluted from the filters with IPTG.

a, Assay for β-galactosidase level was carried out as follows. Plasmid pMB9 is a derivative of plasmid colicin E1 (ref. 3) and, therefore, in the unamplified state, exists in 10–20 copies per cell.

Because there are only about 10 molecules of *lac* repressor per cell, clones containing the *lac* operator ligated to plasmid pMB9 should have all *lac* repressor molecules bound to the *lac* operator on plasmids, leaving the *E. coli lac* operon derepressed, thus producing β-galacto-sidase constitutively. Clones were grown up in 1 ml L-broth containing tetracycline and were screened for β-galactosidase escape synthesis. 0.1 ml of the overnight cultures was diluted to 1 ml, and the cells were lysed with one drop each of CHCl₃ and 0.1% sodium dodecyl sulphate. *O*-nitrophenyl-β-D-galactoside (ONPG) was added to a final concentration of 0.8 mg ml⁻¹. In this qualitative assay[18], a positive indication of constitutive β-galactosidase production was the formation of a yellow colour characteristic of the action of β-galacto-sidase on ONPG. Of the 180 clones tested, three showed high levels of β-galactosidase synthesis. DNA (1 μg) from six clones (including three clones as controls) was labelled by nick translation[18] with DNA polymerase I (7 units) in 100 μl of a mixture containing 50 mM Tris-HCl (pH 7.9), 50 mM KCl, 10 mM dithiothreitol, 10 mM MgCl₂, and 8 μM of the four dNTPs (including α-^{32}P-dGTP, 15 Ci mmol⁻¹). After 2 h at room temperature, the reaction was terminated by ethanol precipitation. Input c.p.m. in the binding assay was between 500 and 1,500 c.p.m. Percentage binding had been corrected for background, determined by results without the addition of the repressor. Background was between 3–6% of the total input counts. *b*, Operator fragment eluted from a gel[7] as in Fig. 2 was found with the repressor as described earlier[17]. Input c.p.m. was between 250 and 600 c.p.m. Percentage binding as shown had been corrected for background which was 2–4%.

Fig. 2 An autoradiograph of gel electrophoresis of hybrid *lac*-plasmids digested with the *Eco*RI enzyme and labelled by repair synthesis[7]. The hybrid *lac*-pMB9 DNA was isolated after amplification by the addition of chloramphenicol to the bacterial culture[15]. The hybrid plasmid DNA (1 μg) was digested with the *Eco*RI enzyme in 20 μl of a solution containing 50 mM Tris-HCl *p*H 7.9, 100 mM NaCl, 10 mM MgCl$_2$ and 3 units of the enzyme (one unit completely digests 1 μg of DNA at 37 °C in 1 h) at 37 °C for 30 min. The reaction was terminated by chilling to 0 °C. The cohesive ends generated by the *Eco*RI enzyme were then repaired by bringing the mixture to a volume of 30 μl containing 70 mM KP$_i$(*p*H 7.0), 10 mM dithiothreitol, 2 μM α-^{32}P-dATP and dTTP (110 Ci mmol^{-1}), and 3 units of DNA polymerase I. After 2 h at 0 °C the reaction was terminated by the addition of 1 volume of 1 M Tris-HCl, followed by two volumes of ethanol. Samples were electrophoresed on a composite slab gel of 3% and 15% polyacrylamide (acrylamide–*bis*-acrylamide = 20:1) with dimensions of 20×40×0.3 cm. The running buffer was 50 mM Tris-acetate (*p*H 7.9). Xylene cyanol FF (XC) and bromophenol blue (BPB) were used as tracking dyes. Electrophoresis was at 150 V for 16 h.
Fig. 3 An autoradiograph of gel electrophoresis of hybrid plasmids partially digested with the *Eco*RI endonuclease and labelled by repair synthesis. The procedures were the same as those given in the legend for Fig. 2, except that 1 unit of the *Eco*RI enzyme and 3 min of incubation were used.
Fig. 4 Strand separation of the *lac* operator duplex. DNA from clone 67 was digested with the *Eco*RI enzyme and labelled by partial repair synthesis by DNA polymerase I using only α-^{32}P-dATP. This now yields DNA fragments with single-strand length of 29 nucleotides. After ethanol precipitation one half the material was dissolved in standard loading buffer and the other half was dissolved in 0.3 N NaOH–10% glycerol. Bromophenol blue and xylene cyanol FF were added to the alkali sample just before loading on a 20×40×0.3-cm 3%:15% step gel of polyacrylmide (acrylamide–*bis*-acrylamide = 20:1). The gel was run in Tris-borate buffer (*p*H 8.3) at 400 V. Two distinct bands corresponding to the separate strands of the *lac* operator fragment can be seen in the slot containing the alkali sample. This can be compared with the mobility of the native fragment which is in the other slot. These bands were eluted and used for sequence analysis as described in the text.

Fig. 5 *a* and *b*, Autoradiographs of two-dimensional electrophoresis–homochromatography of partial DNase digests of the separated strands of the *lac* operator fragment reisolated from hybrid plasmid DNA as in the legend for Fig. 2 and 4. The sequences were deducted by the quantitative mobility-shift analysis[9]. The sequence of 17 nucleotides from one strand and 19 nucleotides from the other strand overlaps by 9 nucleotides to give the sequence of the two 29-nucleotide-long single strands which confirms that 27-nucleotide long sequence as shown in Fig. 1*b*
Fig. 6 An autoradiograph of gel electrophoresis of polymeric *lac* operators. Cloned *lac* operator fragment reisolated from hybrid *lac*–pMB9 DNA by *Eco*RI enzyme digestion was labelled at the 5′ end with ³²P and polynucleotide kinase[9]. The fragment was eluted from a gel and then joined end-to-end with itself (*lac* operator DNA concentration was 130 ng ml⁻¹, using T4 polynucleotide ligase at 12.5 °C. The reaction mixture was analysed on a 10% polyacrylamide gel with a 3% stacking gel, using 40 mM Tris-borate (*p*H 8.3) electrophoresis buffer. When no ligase was used (result not shown), only the monomeric operator (band 1) was present. The lighter bands in between dark bands are presumably circular oligomeric and polymeric *lac* operators.
Fig. 7 Characterisation of a plasmid containing two copies of the *lac* operator in tandem. The band corresponding to a dimer of the *lac* operator fragment was eluted from the gel shown in Fig. 6. This material was then ligated with *Eco*RI endonuclease-cut pMB9 DNA and used to transform HB129 cells. β-galactosidase constitutive clones were identified by their blue colour on X-gal plates[16]. The number of copies of *lac* operator DNA contained in any particular clone was determined by (1) partially digesting (lane *p*) the hybrid plasmid DNA with *Eco*RI endonuclease, and (2) by complete digestion (lane *c*). The digest was then labelled by repair synthesis using α-³²P-dATP and DNA polymerase I. The results were analysed by electrophoresis on a 20 × 40 × 0.3 cm 3%:10% step gel of polyacrylamide (acrylamide–*bis*-acrylamide, 20:1) run in Tris-borate buffer. DNA from clone 67 (marked monomer) are shown for comparative purposes. For experiments with complete *Eco*RI endonuclease digestion, the radioactive DNA bands were cut out from the polyacrylamide gel and counted for ³²P. In the dimeric hybrid, *lac*₂–pMB9 DNA (marked dimer), the ratio of counts in the operator fragment (band 1 in the 10% gel) to the plasmid DNA (the dark band above the 3%:10% junction) was close to 2:1 (60,000 c.p.m:29,500 c.p.m). In the monomeric hybrid (marked monomer) the ratio of counts was 1:1.

Since the yield of *lac* operator from the *lac*–pMB9 hybrid is relatively low, it will be necessary to produce a plasmid with multiple copies of the *lac* operator. To this end, we attempted to determine whether the cloned *lac* operator fragment can be ligated to itself to form polymeric *lac* operators before ligation to the plasmid DNA. Figure 6 shows that one can clearly distinguish on this polyacrylamide gel multi-operator DNA bands which contain up to 18 copies of the *lac* operator (joined together by the protruding sequence 5'pA–A–T–T). These multi-operator DNA molecules appeared to be linear instead of circular in structure as reflected by the percentage of ^{32}P counts released by treating each DNA band (up to the nonamer) with bacterial alkaline phosphatase. A dimeric *lac* operator fragment has been inserted into plasmid pMB9 (Fig. 7). When the hybrid *lac*$_2$–pMB9 DNA was partially digested with *Eco*RI endonuclease a monomeric (band 1) and dimeric (band 2) *lac* operator were found. Insertion of oligo-operator DNA fragments into the plasmid and the characterisation of these hybrid molecules are in progress.

Potential of this technique

The technique described here provides a way of producing large amounts of homogeneous and biologically active *lac* operator DNA for physicochemical studies. The first method (Fig. 1) can also be used to insert any similarly constructed synthetic DNA into a cloning vehicle. The second method[19] which involves end-to-end joining of an even-ended DNA to a synthetic DNA duplex containing the *Bam*I (or other) restriction endonuclease recognition sequence can be used to insert any even-ended DNA molecules into a cloning vehicle. Our technique serves as an example of a general approach in introducing a *lac* operator in front of a gene or a group of genes, so that the gene can be turned on or off by *lac* repressor with or without IPTG.

Blunt end ligation with an EcoRI *octanucleotide "linker" was used to construct a plasmid containing chemically synthesised* lac *operator DNA. This plasmid renders the host bacterium constitutive for β-galactosidase.*

THE specific binding of the *lac* repressor protein to the *lac* operator, a defined nucleotide sequence in the DNA of *Escherichia coli*, controls the expression of the nearby structural genes of the *lac* operon[1]. The nucleotide sequence in the region of the *lac* operator is known[2,3] and recently the *lac* operator (21 nucleotide base pairs, see Fig. 1) has been synthesised by a phosphotriester chemical method[4,5]. This chemically synthesised *lac* operator DNA functions *in vitro*, as evidenced by repressor binding activity[5,6].

To examine the *in vivo* properties of a chemically synthesised genetic element and to have a convenient con-tinuous source of a small *lac* operator DNA, the chemically synthesised *lac* operator was cloned in a bacterial plasmid. The scheme which produced an easily clonable operator DNA fragment is depicted in Fig. 1. Using blunt end ligation by T4 DNA ligase[7], a chemically synthesised octadeoxyribonucleotide containing the *Eco*RI endonuclease recognition sequence[8] was joined to the 21-nucleotide *lac* operator sequence. The resulting RI–operator DNA fragment was then inserted into the plasmid pMB9 (ref. 9) by using the *Eco*RI cohesive termini and established procedures[10]. The pMB9 plasmid was used because it has one *Eco*RI restriction site, carries a tetracycline resistance gene, and can be amplified by chloramphenicol to yield several thousand copies per cell[9,11].

The covalently joined molecules of *lac* operator and *Eco*RI substrate which we refer to as the RI–operator fragment are totally chemically synthesised DNA molecules. The synthesis of β-galactosidase is constitutive in cells

Fig. 1 Experimental plan for cloning of the *lac* operator. The nucleotide sequence at the top of the figure represents most of the control region of the *lac* operon. The 5′ termini are on the left of the upper strands as depicted here. The sites for RNA polymerase binding, mRNA initiation, and so on are depicted[3]. The *lac* operator, where repressor binds, is easily identified by the boxed regions of symmetry. The central operator, where all operator-constitutive mutations occur, is from nucleotide 0 to +20. The extended operator noted by Dickson *et al.*[3], is from −7 to +27. The second line shows the nucleotide sequences of the chemically synthesised DNAs. The 21-nucleotide central operator was synthesised by a phosphotriester method[4,5,18] and the octanucleotide *Eco*RI substrate was made by phosphodiester synthesis[8]. The chemically synthesised DNAs were phosphorylated by polynucleotide kinase, joined by T4 DNA ligase and treated with *Eco*RI endonuclease to produce cohesive ends. The *Eco*RI endonuclease-treated fragment was cloned in the *Eco*RI site of the plasmid pMB9 cloning vehicle[9]. Additional details are given in the legend of Fig. 2.

carrying the RI–operator–pMB9 plasmid because there are about 30 copies of this plasmid per cell in normal growth conditions[9]. The extra operators titrate the 10 to 20 repressor molecules per cell[12], so the single *lac* operon in the host chromosome is not repressed. Therefore, the experiments reported here demonstrate that the genetic constitution of a cell can be altered by the incorporation of chemically synthesised DNA.

The technique devised for cloning the *lac* operator DNA utilises the chemically synthesised octadeoxyribonucleotide containing the substrate for the *Eco*RI endonuclease as a "linker". The addition of short restriction site "linkers" to DNA of any source provides novel flexibility to cloning technology.

Blunt end ligation

Following the procedure given in the legend of Fig. 1, about a 20-fold molar excess of unlabelled *Eco*RI octadeoxyribonucleotide was added to the 5′ ^{32}P-labelled *lac* operator DNA and treated with T4 DNA ligase at 12.5 °C, a temperature slightly below the T_m of the *Eco*RI octanucleotide duplex structure[8]. The *Eco*RI linker was joined to the 21 base pair operator DNA by the blunt-end DNA joining activity of T4 DNA ligase, a property of this enzyme discovered by Sgaramella and Khorana[7] and recently used by W. Gilbert (personal communication) for plasmid construction.

About 50% of the 5′-terminal phosphates on the *lac*

operator DNA were resistant to alkaline phosphatase after a 3-h incubation. A sample of this reaction, along with separate samples of terminally-labelled *lac* operator and *Eco*RI substrate treated separately with T4 DNA ligase, were subjected to electrophoresis on a 12% polyacrylamide gel. An autoradiogram of the gel reveals that the *lac* operator DNA and the *Eco*RI DNA were joined (Fig. 2); the ligated samples of the *Eco*RI linker and the combined *Eco*RI linker plus *lac* operator had molecules of higher molecular weight which must have been formed by the action of the T4 DNA ligase. *Eco*RI endonuclease digestion eliminated the larger molecules, and a new oligonucleotide, 29 nucleotide base pairs in length, appeared.

Cloning

The RI–operator DNA produced by *Eco*RI endonuclease digestion was ligated to *Eco*RI endonuclease-treated pMB9 plasmid DNA and used to transform *E. coli* RR1, which has an i^+z^+ genotype[9]. After 3 h growth for expression of tetracycline resistance, samples of the culture were plated on minimal medium containing 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-gal) and tetracycline. X-gal is not an inducer for the *lac* operon but is a substrate for β-galactosidase[13,14]. After 48 h incubation at 37 °C, 0.3% of the tetracycline-resistant colonies were blue, indicating that these colonies were constitutively synthesising β-galactosidase, and releasing the blue dye 5-bromo-4-chloro-indigo. Since there are about 30 copies of the pMB9 plasmid per

cell and only about 10 *lac* repressor molecules, synthesis of β-galactosidase becomes constitutive if the plasmid contains a functional *lac* operator. Four independent blue colonies were chosen for further studies (plasmid numbers pHH1–pHH4). About a 40-fold increase in the uninduced level of β-galactosidase was observed for each strain.

In vitro characterisation and sequence analysis

Plasmid DNA was prepared from the transformants carrying the independently derived RI–operator plasmids. After *Eco*RI endonuclease digestion, the DNA was treated with alkaline phosphatase, extracted with phenol, and the 5′ terminal labelled with [32]P. The labelled DNA was subjected to electrophoresis on a 20% polyacrylamide gel and the ^{32}P located by autoradiography. Two bands were observed for all four plasmids. These were excised and found to have equal radioactivity, indicating that there is one RI–operator per plasmid. The fastest migrating component was estimated to be 29 nucleotides long, the expected length of the RI–operator fragment (Fig. 2). The short RI–operator fragment was preparatively separated from the 3.5×10^6 dalton plasmid DNA by filtration on Agarose A-50 followed by concentration on hydroxylapatite, or by differential elution from DEAE–cellulose (legend of Fig. 5).

Purified RI–operator DNA from pHH2 was labelled at the 5′ end, alkali denatured and the two short complementary strands separated by electrophoresis on an 8% polyacrylamide gel[15]. The nucleotide sequence was determined by a procedure developed by Maxam and Gilbert (personal communication). The method depends on base specific modification and cleavage of the DNA followed by separation according to length on a 20% acrylamide gel in 7 M urea. The sequence can be read from the autoradiogram shown in Fig. 3. The nucleotide sequence was identical to the 21-nucleotide sequence of the chemically synthesised *lac* operator with an AATTCA sequence at the 5′ end and a TG sequence at the 3′ end (see Fig. 1). The nucleotide sequences of the RI–operator DNA from all four plasmids were compared without separation of the complementary strands and no differences were evident (data not shown).

Repressor binding

The RI–operator in uncleaved plasmid DNA binds repressor very well (Fig. 4). Because supercoils in the plasmid DNA might alter the affinity of *lac* operator for *lac* repressor[16], we converted the pHH2 plasmid DNA to a linear form with *Hin*dIII endonuclease. This enzyme cuts the pMB9 plasmid

Fig. 2 Blunt end ligations and cloning. The chemically synthesised *lac* operator DNA was labelled at the 5′ termini by treatment with T4 polynucleotide kinase (2–5 units per 100 pmol of 5′ ends) in a reaction containing 50 mM Tris-HCl, *p*H 9.5, 10 mM MgCl$_2$, 5 mM dithiothreitol, 5% glycerol and 2 μM γ-^{32}P-ATP (1,000 Ci mmol^{-1}). After 1 h incubation at 37 °C, additional T4 kinase and ATP (to 100 μM final concentration) were added to the reaction and incubation was continued for an additional 30 min to obtain near quantitative phosphorylation of the DNA. The labelled DNA was separated from residual ATP by chromatography on Sephadex G-50. 75 ng of ^{32}P-labelled 21-nucleotide *lac* operator DNA was joined with 550 ng of unlabelled *Eco*RI linker DNA by treatment with 0.4 units of T4 DNA ligase[19] in a 10-μl reaction volume (20 mM Tris-HCl, *p*H 7.6, 10 mM MgCl$_2$, 10 mM dithiothreitol, and 0.4 mM ATP). The reaction was incubated for 3 h at 12.5 °C. For cloning, a sample of the ligated mixture of *Eco*RI linker DNA and operator DNA (about 2.5 pmol of operator) was combined with 0.2 pmol of pMB9 DNA and treated with 50 units of *Eco*RI endonuclease[8] at 37 °C for 60 min in 30 μl (final volume) of 100 mM Tris-HCl, *p*H 7.5, 10 mM MgCl$_2$, 100 mM NaCl, and 0.02% NP40. After inactivation of the *Eco*RI endonuclease by chloroform extraction, 5 μl of 10-times concentrated ligase buffer (0.66 M Tris-HCl, *p*H 7.6, 66 mM MgCl$_2$, 0.1 M dithiothreitol, and 4 mM ATP) and 0.4 units of T4 DNA ligase were added and the volume adjusted to 50 μl. The reaction was incubated for

16 h at 12 °C, dialysed against 30 mM CaCl$_2$, and used to transform strain RR1[9] according to an established procedure[10]. The transformed culture was plated on glucose minimal medium[11] containing 40 μg ml^{-1} of 5-bromo-4-chloro-3-indolyl-β-D-galactoside and 10 μg ml^{-1} of tetracycline. There were approximately 5,000 tetracycline resistant transformants per ml of culture. The reaction was followed by electrophoresis of the products in a 12% polyacrylamide gel containing 7 M urea, 50 mM Trisborate *p*H 8.3, 1 mM EDTA. An autoradiogram (Kodak NS X-ray film) of the gel is shown. Migration of the DNAs is from top to bottom. Lane 1: ^{32}P-labelled *lac* operator DNA. The slowest migrating band contains the intact operator DNA strands and the faster migrating components are presumably incomplete reactants or other contaminants. Lane 2: Ligated mixture of unlabelled *Eco*RI-linkers and ^{32}P-labelled *lac* operator DNA. Distinct oligonucleotide bands larger than the 21-nucleotide *lac* operator are evident and represent the operator DNA to which one, two, three or more *Eco*RI-linkers have been ligated. Lane 3: *Eco*RI digested ligation mixture. Treatment of the material shown in lane 2 with *Eco*RI restriction endonuclease reduces the large molecules to a size equal to or smaller than the RI–operator shown in lane 4. Thus the majority of the ligated material seen in lane 2 represents operator DNA bounded by *Eco*RI-linkers rather than multimers of the *lac* operator DNA. Lane 4: RI–operator DNA purified from the plasmid pHH2. The purification and ^{32}P-labelling of the RI–operator are described in the legend to Fig. 3.

Fig. 3 DNA sequence analysis of the RI–operator fragment. Purified pHH2 plasmid DNA was treated with *Eco*RI endonuclease to release the small operator fragment. The cleaved DNA was dephosphorylated by treatment with alkaline phosphatase (1 unit per 200 pmol of 5′ termini in 25 mM Tris-HCl, *p*H 8.0, 1 mM EDTA), followed by phenol extraction and G-50 Sephadex gel filtration. The dephosphorylated DAN was ³²P-labelled as described in the legend of Fig. 2. The small RI–operator DNA was separated from the 3.5 megadalton linear plasmid DNA by chromatography on DEAE–cellulose. The RI–operator DNA was eluted with 0.8 M triethylammonium carbonate at *p*H 8.0 and concentrated by lyophylisation. The complementary strands of the RI–operator were separated by denaturation in 0.1 M NaOH followed by electrophoresis on an 8% polyacrylamide gel in 50 mM Tris-borate *p*H 8.3, and 1 mM EDTA[15]. The two strands separated completely and, after elution from the gel, were used for sequence analysis. The sequence determinations were carried out according to a protocol kindly supplied by Maxam and Gilbert (to be published). The procedure depends on base specific cleavage of 5′-labelled DNA, followed by separation of the fragments according to size by electrophoresis on 20% acrylamide gels under denaturing conditions (7 M urea). Preferential cleavage at guanosine residues was achieved by methylation with dimethylsulphate, depurinisation by heating to 90 °C at *p*H 7.0, followed by alkali treatment. Cleavage at adenosine residues was achieved by depurinating the methylated DNA at 0 °C for 1 h in 0.1 N HCl. Preferential modification and subsequent cleavage at cytidine residues was obtained by treatment with hydrazine in the presence of 1 M NaCl. Cleavage at thymidine residues results when hydrazine treatment is carried out in the absence of NaCl. The darkest band at each fragment size indicates which condition caused preferential cleavage, and thus identifies the base at which cleavage occurred to give the fragment. In practice, each cleavage condition is only partially specific, but the cleavage pattern for all four conditions run in parallel allows the sequence to be determined, especially when both strands are analysed. The right four lanes of the autoradiogram shows the cleavage pattern for the upper strand. The left four lanes show the lower strand. For each set the G-specific cleavage is on the left followed by A-specific, T-specific, and C-specific. The first two nucleotides at the 5′ end of each strand were not determined by this method but are known from the specificity of *Eco*RI endonuclease.
about 200 base pairs from where the RI–operator is located[9]. Linear pHH2 DNA competes even more effectively for repressor; only a threefold molar excess gives 50% competition with ³H-λ*plac* DNA. This result strongly suggests that when the RI–operator is sequestered in high molecular weight DNA, it has an affinity for repressor close to that of natural *lac* operator.

Direct filter binding experiments with purified ³²P-labelled RI–operator DNA fragments were also done and they demonstrate clearly that the small RI–operator DNA fragment binds *lac* repressor (Fig. 5). The filter retention is eliminated by isopropylthiogalactoside (IPIG), an inducer of the *lac* operon. The plateau of filter retention is only 20% for the RI–operator DNA, whereas the filter retention

of λ*plac* DNA is usually about 50%. The lower retention efficiency for the RI–operator DNA probably is a reflection of the lower binding affinity of the small fragment for repressor. Our preliminary competition data indicate that the excised RI–operator fragment has at least a 100-fold reduced affinity for repressor, compared with intact pHH2 plasmid DNA.

Chemically synthesised DNA and cloning

In this paper and the paper by Marians *et al.*[17], are reported the first successful construction of plasmids carrying a functional genetic element derived from chemically synthesised DNA. The plasmids described here carry the 21-nucleotide sequence of the *lac* operator bounded on both

Fig. 4 Competition for *lac* repressor by plasmid DNA. Various amounts of unlabelled plasmid DNA were mixed with 0.025 µg of ³H-λ*plac* DNA and then an equimolar amount of *lac* repressor was added. This amount of repressor was found to give 85% saturation of the operator in ³H-λ*plac* DNA in the absence of competing DNA. The reaction volume was 0.4 ml and the buffer was 10 mM KCl, 10 mM Tris-HCl (*p*H 7.4), 0.1 mM EDTA, 0.1 mM dithiothreitol, 5% (v/v) dimethyl-sulphoxide, and 50 µg ml⁻¹ of bovine serum albumin. After 30 min incubation at room temperature, 0.15-ml aliquots were filtered in duplicate through nitrocellulose filters according to the procedure of Riggs *et al.*[20], and washed once with 0.2 ml of buffer without bovine serum albumin or dithiothreitol. ●, pMB9 plasmid DNA; ○, pHH2 plasmid DNA; △, *Hind*III endonuclease-treated pHH2 plasmid DNA.
Fig. 5 Binding of *lac* repressor to purified ³²P-RI–operator DNA. The purified small RI–operator fragment was labelled with ³²P-phosphate by T4 polynucleotide kinase treatment. Varying amounts of *lac* repressor were added to 2.6 ng of purified RI–operator DNA. The reaction volume was 0.5 ml and the buffer was that used in Fig. 4. After 20 min at room temperature, 0.2 ml aliquots were filtered and washed as in Fig. 4. ●, No IPTG; ○, 10⁻³ M IPTG.

find that the RI–operator sequence, when it is sequestered in large molecular weight DNA, has an affinity for repressor within a factor of three of that of natural *lac* operator in λ*plac* DNA. Therefore, the symmetrical sequences in the "extended operator" are not obviously involved in this protein–DNA interaction. When RI–operator is cut from the plasmid DNA, the affinity for repressor is lowered greatly. Therefore, it seems necessary to have DNA on both sides of the 21-base-pair operator for "normal" interactions, but the sequence of this DNA is probably not critical.

The method used to generate the RI–operator fragment, that of the blunt end joining of a short restriction enzyme substrate (linker) to each end of the DNA of interest, is generally useful for DNA manipulation and cloning. For example, *Eco*RI "linkers" or other endonuclease substrate linkers now can be added to any blunt ended DNA molecule. The combination of chemical synthesis technology with cloning technology will provide a powerful approach to many problems, including the chemical synthesis of long DNA sequences.

sides by *Eco*RI endonuclease restriction sites. The *lac* operator cloned in the plasmids functions *in vivo* by binding the available *lac* repressor molecules, resulting in the constitutive synthesis of β-galactosidase. *Eco*RI endonuclease can be used to excise the small RI–operator fragment from the plasmid DNA. Therefore, this plasmid provides a continuous source of a small *lac* operator DNA, which will greatly facilitate many physicochemical and other experiments. We are now trying to construct plasmids containing several RI–operators polymerised in tandem. Such a polyoperator plasmid will provide enough *lac* operator DNA for crystallisation of repressor–operator complexes and the structural analysis of the mechanism of a sequence-specific protein–DNA interaction.

These studies show that the 21-nucleotide sequence of the "central" lac operator provides for almost all of the specific *in vitro* interactions with *lac* repressor. As shown in Fig. 1, Dickson *et al.*[3] noted additional regions of symmetry on each side of the central 21-base-pair operator. This observation led to speculation that the repressor might interact specifically with a larger DNA sequence (35 base pairs). We

The hard X-ray spectrum of Cyg X-1 during the transition in November 1975

We wish to report an observation of the hard X-ray spectrum of Cyg X-1 during a transition to the high state in November 1975. The measurement was obtained with a balloon-borne X-ray detector in the 25–150 keV range. This third upward transition of Cyg X-1 in 1975 was also detected in the few-keV energy range by the Ariel V all-sky monitor (S. S. Holt, L. J. Kaluzienski, E. A. Boldt, and P. J. Serlemitsos, unpublished). Our high energy data seem to confirm the characteristic spectral time variation of Cyg X-1: a soft X-ray intensity

increase is correlated with a decrease of the hard X-ray intensity. The similarity of Cyg X-1 and the transient source A0620 00 with respect to such spectral variation has been pointed out by Coe *et al.*[1].

Cygnus X-1 was observed on November 4, 1975 from 2245 until 2330. The apparatus was launched from Palestine, Texas and floated for 5.5 h at an altitude corresponding to a pressure of 4.3 g cm⁻². The data were obtained with an array of six 100-cm² NaI (Tl) detectors which are part of an X-ray burst experiment under construction. The counts of each detector were sampled in four energy channels for equal periods of time. The data handling as well as the film recording were designed
Fig. 1 Spectra of the X-ray source Cyg X-1. The black dot and hatched area indicate average spectra of Cyg X-1 in the 'normal state'. ○, Daily averages of the intensity in the 3–6 keV band for three successive days during the upward transition of Cyg X-1 (from ref. 4). The crosses are our data.

to suit the apparatus on future transatlantic balloon flights. In this short test flight we used a $4 \times 22°$ passive collimator to separate X-ray sources. The gondola was orientated by an azimuth control system. The background flux was observed shortly before and after the Cyg X-1 exposure. In the 30–60-keV range, 7×10^{-3} counts $cm^{-3} s^{-1} keV^{-1}$ were found. After subtracting the background we fitted a power spectrum to the data taking into account absorption, collimator response, energy resolution and the probability of escape of an iodine K photon. All detectors were calibrated by measuring the 60-keV line of a ^{241}Am radioactive source and the iodine escape peak at ~ 30 keV.

The resulting X-ray intensity of Cyg X-1 is shown in Fig. 1. For comparison we plotted typical normal state spectra of Cyg X-1, which are remarkably constant as often observed. The soft X-ray intensity data (from ref. 4) are daily averages for November 4, 6 and 5, 1975. Our data combined with the soft X-ray measurements suggest a single power law spectrum from 3 to 80 keV with an increasing spectral index during the upward transition of Cyg X-1 to the high state.

A power spectrum is expected if one assumes the inverse Compton effect as the basic mechanism which produces the hard X-ray tail of Cyg X-1 (ref. 2). These models require a very luminous source of soft photons inside an optically thin, hot ($kT_c \simeq 100$ keV) disk. Spectral time variation may be caused by a varying intensity of the inner soft photon source and a stable hot cloud. Spherical accretion on to a black hole has been suggested (ref. 3 and U. Anzer, G. Börner, and P. Mészáros, unpublished). Temperatures of $> 10^9$ K may be produced by the dissipative heating of the infalling gas. The X-ray spectra could then arise from bremsstrahlung which would also explain the spectra.

Ball lightning as electromagnetic energy

NONE of the theories[1-8] proposed to explain ball lightning seems able to account satisfactorily for the experimental evidence[9-14]. Jennison[15] has suggested that ball lightning is a spherical stable standing wave of electromagnetic radiation. The proposal that ball lightning in effect consists of electromagnetic field energy trapped in an evacuated cavity of approximately spherical shape, with an ionised sheath separating it from the atmosphere, merits further examination.

The energy density inside the ball will be magnetic ($B^2/2\mu_0$), electric ($\varepsilon_0 E^2/2$) or both. For equilibrium, the ball must exert an average pressure at all points on its surface equal to atmospheric pressure. The standard boundary conditions for a microwave cavity with conducting walls are **E** normal and **B** tangential to the boundary. For these conditions the outward electromagnetic pressure is $[(B^2/2\mu_0)—(\varepsilon_0 E^2/2)]$. Now the largest estimate[1,9] of the energy density in a ball ($\sim 4 \times 10^9 J m^{-3}$) is 4×10^4 times the atmospheric pressure expressed as an energy density. The average magnetic energy density at all points on the surface of the ball must therefore be very nearly equal to, but slightly greater than, the average electric energy density. This is the main difficulty, but further problems include stability, power loss and mechanism of formation of the ball.

A mechanism consistent with recently reported observations[16], for the formation of a simplified 'cylindrical' ball is depicted in Fig. 1. A cloud of positive space charge is attracted towards a negative leader stroke as it approaches the ground (Fig. 1a). There is some misalignment, however, which causes parts of the two regions of space charge to spiral around each other (Fig. 1b). The end result is an electric dipole configuration rotating in the atmosphere just above the ground (Fig. 1c). This departure from the normal cloud to ground discharge mechanism requires an appropriate asymmetry in the geometry (for example, a small building or a tree[9] in the immediate vicinity). It is therefore a comparatively rare event, as required by the observed incidence of ball lightning[16]. It is well known from data on lightning return strokes[1], that once the atmosphere has been ionised, the speed of a lightning stroke can exceed $10^8 m s^{-1}$. It is an important feature of this model that the peripheral speed of the final dipolar rotating field pattern should be $> c$, the velocity of light. Given that the space charge regions are not reduced to charges of one sign only, this is quite possible, since there is then no requirement for individual charged particle velocities to be $> c$, (phase velocities $> c$ are commonplace in wave-guides and in pulsar rotating fields[17], both of which have features in common with this model).

A sketch of a rotating electric dipolar field pattern in a long cylindrical cavity is shown in Fig. 2. The return path for the current I in the wall is by way of the displacement current in the cavity which may be written as $(\nabla B \cdot \hat{Z}/\mu_0)$. The vacuum field inside the cavity may be obtained by solving the equations

$$\nabla^2 B - (\omega^2/c^2)\partial^2 B/\partial\theta^2 = 0$$

$$(\nabla B \cdot \hat{Z}) = (\omega/c^2)[r\partial E_r/\partial\theta - \partial\partial E_\theta/\partial\theta] = 0$$
Fig. 1 Successive stages (*a–c*) in the suggested mechanism of ball lightning formation.

subject to the condition that **E** is normal to the boundary. The *r*— component of the second equation gives, for the rotating dipolar field considered

$$B = -(r\omega/c^2)E_r$$

Thus at the boundary (radius *a*), where E_θ is zero, the net outward electromagnetic pressure is

$$(B^2/2\mu_0) - (\varepsilon_0 E^2/2) = (B^2/2\mu_0)[1 - (c^2/a^2\omega^2)]$$

Therefore the peripheral velocity (*a*ω) has to be > *c* so that the net electromagnetic pressure be directed outwards. The electromagnetic pressure does of course vary with rotation angle, but the frequency is too high for the atmosphere to respond appreciably to the variations. The ratio of the electromagnetic energy density to the electromagnetic pressure at the sheath and hence to the atmospheric pressure, can be made as large as is required to fit the observations. The particles in the sheath will move at the convective velocity ($E \times B/B^2$) with a small counter-streaming velocity superimposed. In the frame moving at the convective velocity the radial electric field is zero and a small outward ($J \times B$) force balances the atmospheric pressure. Compared with the radial component of electric field in the rest frame, the tangential electric field in the sheath associated with the small counterstreaming (conduction) current will be negligible. The ball does not discharge internally because the radial electric field seen by the convected sheath is zero.

For an energy density in the ball of 4×10^8 J m^{-3}, the asso-

Fig. 2 Schematic diagram of a rotating electric dipolar field pattern in a long cylindrical cavity with conducting wall. No attempt has been made to show retardation of the field.
ciated values of *E* and *B* are $\sim 2 \times 10^{10}$ V m^{-1}, and 70 T respectively. For a cylinder of ~ 10 cm diameter[9] and 30 cm length, the total energy is $\sim 10^7$ J, that is, 1–10% of the energy available in a typical lightning discharge; and the charge is 0.02 C, which is $\sim 10\%$ of a typical leader charge[1], suggesting that only a fraction of the leader charge goes into formation of the ball, the remainder discharging to ground in the normal way (Fig. 1*b*).

In principle there is no difficulty in extending this model to the spherical case. To avoid nodes of zero electromagnetic pressure on the rotation axis, additional precessional velocities need to be introduced. Any air penetrating the surface of the ball near the rotation axis will be rapidly ionised and expelled. The forces required are likely to be provided by a secondary flow of conduction and convection currents across the rotation axis, so that the ball effectively generates its own precessional mechanism. The average electromagnetic pressure can then be made the same at all points on the surface, as required for equilibrium. This field computation would, however, be very complicated. Nevertheless, the most stable configuration is the most likely to occur in practice, and is likely to be approximately spherical, although any rapidly precessing volume of revolution would be indistinguishable from a sphere by the naked eye. The exact shape to be expected would depend on detailed energy considerations. The MHD instabilities that occur in plasma confinement experiments are not likely to occur with this model, because the field is inside rather than outside so that the boundary curvature is everywhere favourable, and also because there will undoubtedly be a high degree of shear in the boundary magnetic field. The wall current is likely to be largely convective, with only small conduction currents needed to keep charge velocities < *c*. Power loss through ohmic heating of the sheath is therefore expected to be small.

There is also likely to be a small leakage of the field through the sheath, which could be sufficient to maintain the ball at a steady distance from surrounding structures, but insufficient to cause motion in small metal objects nearby[15]. On the other hand, strong interaction with metal objects penetrating the surface of the ball would be expected[14]. The energy in the ball could either be entirely dissipated by ohmic heating of the sheath and radiation through it, in which case the ball would disappear quietly, or it could be dispersed by a perturbation leading to an instability, in which case the ball would disintegrate explosively. Both explosive and non-explosive terminations have been observed[4]. There is no reason, according to this model, why ball lightning should not drift into buildings[11], or be found in aeroplanes[10], since it transports its own energy. In the latter case, the ball would either have to pass through a glass window, or be formed inside the aeroplane. If in fact lightning were to strike an aeroplane near one of its windows, it is quite possible that sufficient electric field and ionisation would be set up inside the aircraft for ball formation to occur as described here. The metal surrounding the window would take the place of the ground, and the geometry would favour the necessary spiralling motion.

Undoubtedly this model will require modification as further characteristics of ball lightning become established. It does suggest, however, that the electromagnetic field inside the ball is likely to be the energy source rather than nuclear reactions[1], antimatter[7], continuous energy input from an external field[5,6], or unusual forms of gas discharge energy[2,3].

Radiocarbon chronology of late Quaternary lakes in the Arabian Desert

A GOOD deal of information on late Quaternary moist periods in East Africa and Australia, derived largely from the dating and analysis of lake sediments, has been collected over recent years[1–4]. Although fossil lake beds have long been known to exist in Arabia[5–7], they have received scant attention. I report here the results of a preliminary attempt to establish the age of a series of late Quaternary lake sediments in the Rub' al Khali desert of the Arabian Peninsula. More detailed palaeoclimatic implications will be considered elsewhere later.

The Arabian Peninsula (Fig. 1) is essentially a plateau which dips gently towards the north-east and can be sub-divided into a western (Precambrian) igneous shield and an eastern province of sedimentary rocks. Alluvial sands, gravels and silts obscure a dendritic drainage system which was established in Quaternary times[7–9]. These sediments are in turn partially blanketed by wind-laid sands, especially in the eastern basins. The largest of these basins is the now extremely arid Rub' al Khali.

Lacustrine deposits are intimately associated with the aeolian and alluvial deposits and, though insignificant in dimensions, hold the key to the late Quaternary geomorphological and climatic evolution of the area. The deposits consist of calcareous and often fossiliferous marls, clays and silts. They characteristically form flat-topped benches and mounds, often on the lee of longitudinal dunes and in the 'corridors' between the dunes where recent deflation has removed the superficial deposits. Stratigraphical and morphological criteria indicate the presence of two main generations of lake beds, the older resting on alluvium, and the younger on aeolian sands which antedate the modern (red) dune sands. The lake beds seem to reflect centripetal runoff into deflated hollows.

Fossil Lake Mundafan (Fig. 1), one basin in which both sets of deposits are represented, displays 24 m of lake beds

MF 23	UGa-1210	Marl	14,965 ± 195

*MF refers to Lake Mundafan samples. Sites of other samples are indicated in Fig. 1.

interstratified with alluvial and aeolian sands. The principal sources of runoff were probably the backslope of the eastward-dipping Wajid plateau and the foreslope of the eastward-dipping Al Arid (Jabal Tuwaiq) escarpment. The lake beds of the Mundafan basin are thought to extend beneath the alluvium and aeolian sands 150 km northward along the Al Arid escarpment.

Radiocarbon dating of lake beds from the Mundafan basin and from five other smaller depressions further inside the Rub' al Khali (sites 1–5 in Fig. 1) supports the contention that two main periods of high water level occurred in the area during the late Quaternary. The dates (Table 1) place the first period (series A) between ~36,000 and 17,000 yr b.p., with a concentration of dates between 21,000 and 30,000 yr b.p., and the second period (series B) between ~9,000 and 6,000 yr b.p. A third period of minimal and low-lying lake bed deposition (series C) separates the two.

At Lake Mundafan, extensive wind erosion, local slumping, possible changes in basin configuration, and the fluctuating nature of the various water levels combine to complicate stratigraphic relationships of the beds from which the dated material derives. Details remain to be worked out. Generally, beds of Series A occupy high parts of the basin and beds of series B and series C occupy low parts.

The dates reported here are in close agreement with dates reported from East Africa and Australia[1–4]. Additional dates and further analysis of Arabian lake bed material should help define more precisely the late Quaternary palaeoclimatic sequence of the area.

Effect of magnetic field on reduction of nickel oxide

"In 1872, US patent No. 133099 on the use of a magnetic coil for 'Improvement in Reduction of Ores, etc.' was granted to Abraham T. Hay, of Burlington, Iowa[1]. It was a failure." Thus stated Skorski[2] who a century later reported that the reduction rate of haematite (Fe_2O_3) with H_2 was considerably enhanced by application of 500- and 1,400-oersted magnetic fields as compared with reduction in the Earth's field (~0.5 oersted). Skorski[2] also used CH_4 and CO for the reduction, but found the rate in these cases was slower in a strong magnetic field than in the Earth's field. He concluded that the effect must be dependent on the magnetic properties of H_2 itself rather than on those of Fe and its oxides. This notion was immediately challenged by Svare[3] who demonstrated that the magnetic properties of H_2 are not significantly different from those of CO and CH_4 in the context of the reaction involved. Peters[4], however, argued that the observed acceleration in reaction rate is predictable from thermodynamics theory when product and reactant species differ widely in their magnetic properties—as do Fe_2O_3 and metallic Fe (or NiO and metallic Ni) for example.
Fig. 1 Variation of the saturation magnetisation of Ni metal with temperature, as recorded by the electrobalance used in this work. Note that the apparent weight (saturation magnetisation) of Ni is much greater than its actual weight.

One can readily view this argument qualitatively in terms of Le Chatelier's principle.

We recently began a systematic study of the effect of a strong magnetic field (~4,200 oersted) on oxidation–reduction systems involving strongly magnetic products of reactants. The Fe-iron oxide system is, however, relatively complicated

$$Fe_2O_3 \longrightarrow Fe_3O_4 \longrightarrow Fe \quad (< 550\ ^\circ C)$$
haematite   magnetite   metallic iron
Thus Skorski[2] examined the above reduction on an 'observation after the fact' basis—the final product probably being an unknown mixture of Fe_2O_3, Fe_3O_4 and Fe. The interpretation of results is thus considerably complicated.

We present here results using a sensitive technique whereby observations are continuously recorded on a real-time basis during constant temperature reduction of NiO to Ni. Since Ni is ferromagnetic whereas NiO is paramagnetic, Peters'[4] criterion
Fig. 2 Schematic diagram of the Cahn electrobalance used in this work. The system continuously records the weight of the sample as the reaction proceeds.

that product and reactant magnetic properties differ widely is met. We thus incorporated two distinctive features into our work: first, we selected a simple metal–metal oxide system; only NiO and Ni are involved. Only NiO occurs in the ordinary chemistry of nickel. Higher oxidation states of nickel are quite

Fig 3 Reduction of NiO to metallic Ni with 65 ml min^{-1} flow of 20% H_2 in N_2 carrier at 295 °C. This experiment was conducted in the Earth's magnetic field. Points were hand-read from a strip chart recording for construction of Figs 3 and 4 so they could be directly compared. The mass data were recorded continuously: □, 2.90 mg NiO; +, 3.08 mg NiO; ●, 0.92 mg NiO; and ○, 1.14 mg NiO. The solid bold line through the data points is a least squares best fit straight line fitted to the points from 0 to 20 min. It is for comparison only.
unstable; second, we continuously monitored the course of the reaction.

The behaviour of Ni in the presence of a large magnetic field ($\sim$4,200 oersted) is well known, as is the temperature dependence of this behaviour (illustrated in Fig. 1 for our system). This behaviour was determined by suspending a small sample from a sensitive balance (see Fig. 2). The application of a strong inhomogeneous magnetic field to the sample results in a force of attraction—measured as an apparent weight which is many times greater ($\sim$40 times for Ni) than the actual weight of the sample. The apparent weight (saturation magnetisation) decreases with increasing temperature until it essentially vanishes at the Curie temperature. Heating and cooling curves were indistinguishable.
Fig. 4 Reduction of NiO to metallic Ni. Experimental conditions were the same as those in Fig. 3, except that a strong magnetic field ($\sim$4,200 oersted) was applied here. $\square$, 2.58 mg NiO; $+$, 1.29 mg NiO; $\bullet$, 2.08 mg NiO; and $\bigcirc$, 2.87 mg NiO. The line is again a least squares best fit to the data exhibited in Fig. 4 in the early portion (0–20 min).

To monitor the change in NiO and Ni during the course of the reduction of NiO without application of a magnetic field, 20% H_2 in N_2 carrier was passed through the balance system (Fig. 2 with the magnet removed) for $\sim$ 1 h to thoroughly flush the system with 1–3 mg samples of NiO in place. The temperature was then quickly raised to 295 $^\circ$C ($\sim$10 min) and the weight of the sample was continuously recorded as a function of time. The observed weight change directly reflects the relative amounts of Ni and NiO in the sample at any time. The early portion of the curve in Fig. 3 ($\sim$0–20 min) was approximately linear and the bold central line shows a least squares best fit to the average of the four runs. Each of these runs were conducted in the Earth's magnetic field ($\sim$0.5 oersted).

To ascertain the change in this reduction rate (if any) caused by the application of a strong magnetic field, we used the same experimental system (Fig. 2) but with the $\sim$4,200 oersted magnet in place to influence the sample during the course of the reduction. In this case the apparent weight change was greatly exaggerated during the course of the reduction as the non-magnetic (paramagnetic) NiO was converted into ferromagnetic Ni, which under the influence of the magnetic field

yielded an apparent weight many times the actual weight of the sample (Fig. 1). Again four independent reductions, this time carried out under a strong magnetic field, were conducted and the results are shown in Fig. 4. Again a least squares line was fitted to the approximately linear portion of the curve. The difference in slope between the line in Figs 3 and 4 was only 1.3%, well within our experimental uncertainty. It is apparent from an examination of Figs 3 and 4 that any difference in the reduction rate of NiO, with or without the application of a magnetic field, is quite small and is not discernible by our technique.

We now intend to investigate the more complex iron–iron oxide system maintaining control over reaction products by carefully mixing reaction gases so as to produce an oxygen fugacity in which the desired product is stable whereas the others are not[5].

Charge transport by solid particles in liquid dielectrics

ONE of the more controversial aspects of the study of liquid dielectrics has been the role of natural particles in the mechanism of charge transport (see, for example, the recent review by Gallagher[1] and references therein). Theoretical estimates of the charge carried by individual particles are discrepant by several orders of magnitude. However well purified and filtered a liquid sample may be, as soon as it is subjected to electrical stress such particles may be seen in motion between the electrodes by observing scattered light from them through a microscope. They are of indeterminate composition and $\sim$ 1 μm in diameter. In the first attempt to make a direct study of charge transport by natural particles[2] reliance had to be placed on a correlation involving the human senses, which was valid for low voltages and was assumed to be capable of extrapolation to higher voltages, where speeds are too great for such methods to be used. Also, since the particles exhibit a dwell-time on the electrodes which is very much greater than the transit time the experimental problem of capturing the charge waveform is considerable. Here we report preliminary results of an attempt to correlate the waveforms formerly attributed to solid particles with physical evidence of actual particle motion obtained by observation of the light scattered from them.

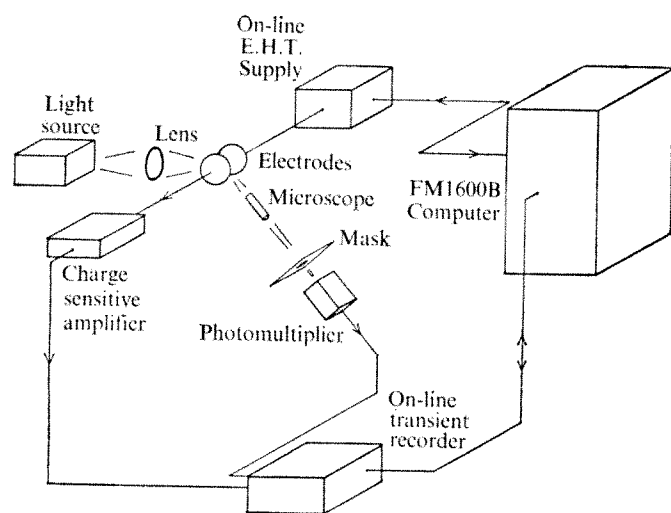
As a problem in measurement this is one of intriguing complexity. It is necessary to capture two fast waveforms, a charge signal of the order of femto coulombs and a light signal of the order of a tenth of a lumen. These signals occur at random and are corrupted by noise. Indeed, the first attempt to be made to record the motion of a particle by means of scattered light failed. This involved focusing the image of the centre of the gap on to the cathode of a photomultiplier, the image of the electrode surfaces being masked off. Unfortunately, the


Fig. 1 Experimental arrangement for the simultaneous monitoring of motion and charge transport by natural particles. The 1-cm diameter spheres are 100 μm apart, and light scattered through 50° is collected by the microscope. The mask at the real image surface selects one electrode surface for transmission to the photocathode. The light and charge waveforms are captured by the on-line transient recorder and transmitted to the computer.

combination of high speed and low level of scattered light produced a signal which was irretrievable from noise. It was found, however, that if the image of one electrode surface was projected on to the photocathode, the arrival and departure of particles could be recorded as step waveforms in the light scattered at the electrode.

Fig. 2 Captured waveforms from the on-line incremental plotter. *a*, A typical step produced by a particle leaving the electrode. There is a slight delay from noise filtering. *b*, The corresponding charge waveform. The decay following the step rise is introduced artificially. *c*, The result of averaging 36 charge waveforms. These were adjusted horizontally to maximise registration of the corresponding light waveform steps.

Scattered light waveform

Charge waveform

Cumulatively averaged charge waveform
Figure 1 shows the experimental arrangement in diagrammatic form. The photomultiplier is placed at an angle of 50° to the axis of incident light and the mask is set so that scattered light from only one of the pair of spherical electrodes is recorded. Meanwhile a charge-sensitive amplifier is used to monitor the increments of charge at the cathode (though as is the practice with nuclear detectors, an artificial decay is provided in the response to prevent the 'buildup' which would saturate the amplifier). The residual problem of recording and correlating these randomly occurring waveforms was until recently a formidable one, but the introduction of the on-line transient recorder[3-5] has made it quite simple.

Figure 2*a* and *b* shows scattered light and charge waveforms recorded simultaneously by the transient recorder and plotted by the on-line computer. It will be seen that there is a coincidence suggesting that the characteristic charge transient is indeed the product of charge conveyance by a solid particle. Single instances, however, do not establish a definite correlation, and to do this the following experiment was conducted.

Pairs of waveforms like those in Fig. 2*a* and *b* were acquired repetitively at random by the on-line transient recorder. Owing to the effects of noise in the light waveforms, which are used to trigger the transient recorder, slight misalignment can occur between one light waveform and another. Therefore, within the computer the waveform pairs were shifted slightly to give best registration of the light waveforms only. Meanwhile the corresponding charge waveforms were cumulatively averaged. The sharp artificial decay is advantageous in this application since it yields a short pulse which is more difficult to register and therefore is a more demanding test for correlation. The results of 36 such repetitions are shown in Fig. 2*c*. While the shape of the charge waveform is naturally lost, its repeated correlation with the step in the scattered light establishes conclusively that particle motion is responsible for the small charge or current pulses observed in all dielectric liquids under electric stress. The speed of the equipment used allows this correlation to be observed up to stresses of 46 MV m^{-1} in *n*-hexane.

The strong grounds for accepting that the waveforms relate to particle motion are not only that other possible mechanisms are not consistent with such well defined transitions, but that the shapes are invariant from low stresses, where particles can be visually observed, through the whole stress range.

These studies confirm, first, that particles are directly responsible for much of the randomly fluctuating component of current in stressed liquid dielectrics, but second, that the charge carried by individual particles is very low and corresponds to a potential of only ∼ 15 V (refs 1, 2, 4). Perhaps even more significantly in terms of physical processes, they have not yet revealed any correlation between particle activity and the large (pC) pulses which have been observed by several authors to occur irregularly at high stresses. The ill-defined shape and duration of such pulses makes them difficult to study, even with the powerful on-line techniques mentioned above, and such a study is the object of our present work.

Three modes of dissociation of H bonds in hydrogen-bond dominated solids

ICE, paper and regenerated cellulose, Nylon (unstretched and lightly stretched), and to a certain extent natural cellulose, lignin and wool are typical examples of hydrogen-bond dominated solids (whose mechanical properties are mostly controlled by the density and characteristics of the hydrogen bond). Previously[1] I have shown that for these materials, Young's modulus E is related to N, the effective number of H bonds per cm³ responding to unidirectional stress, by $E = kN^{1/3}$. For cellulosics k is ~ 8×10^2 when E is in Pa. Two major rheological characteristics of hydrogen-bond dominated solids are their ready softening by water and their relaxation of stress with time under constant strain. Thus, E_w/E_0, the ratio of the modulus at w g H_2O/g solid to the modulus at $w = 0$, drops to very small values for paper at saturation. Similarly, E_t/E_0, the modulus at time t to E at $t = 0$ in a stress relaxation experiment, drops to small ratios at high values of t. I postulate that both types of loss in E arise from reductions in N, through H-bond dissociation. I find this dissociation can be in one of three modes: I, II and III.

Mode I dissociation occurs on wetting a hydrogen-bonded solid within the range, $0 < w < w_c$ where w_c is a critical moisture content designating transition from mode I to mode II. w_c is postulated to be equal to w_m, the moisture content for a monomolecular layer calculated by BET equations[17] applied to the adsorption isotherm of water on the particular polymer. Mode II occurs when $w_c < w < w_{sat}$ where w_{sat} denotes the water saturation value of w. Further, let N_0 be the value of N at $w = 0$ and W be the hypothetical value of w which allows one H_2O molecule for each potential H bond in the solid. (For cellulosics, with potentially six H bonds existing per repeat unit of cellobiose, $W = 1/3$.)

In mode I we begin with

$$d(N_w/N_0)_1 = -(N_w/N_0)_1 d(w/W) \quad (1)$$

and arrive at

$$\ln(E_w/E_0)_1 = (-1/3)(w/W) \quad (2)$$

(The suffix 1 denotes mode I.) Hence, specifically for cellulosics

$$\ln(E_w/E_0)_1 = -w \quad (3)$$

This has been demonstrated for paper for $0 < w < w_m$ (ref. 1).

In mode II, dissociation is cooperatively undertaken by a number of bonds breaking down together. I use here Frank and Wen's hypothesis[2] of H bonds making and breaking co-operatively together in flickering clusters. Thus, I postulate that a molecule of water initiates the cooperative phenomenon by breaking only one bond, but this triggers others to break immediately. The total number is equal to the cooperative index (CI) but the reaction is still unimolecular in N. Thus

$$d(N_w/N_0)_2 = -(\overline{CI})(N_w/N_0)_2 d(w/W) \quad (4)$$

with initial condition at $w = w_c$

$$\ln(N_w/N_0)_2 - \ln(N_w/N_0)_1 = -(w_c/W) \quad (5)$$

Hence

$$\ln(E_w/E_0)_2 = (1/3)\{(w_c/W)[(\overline{CI}) - 1] - (\overline{CI})(w/W)\} \quad (6)$$

For cellulose, $W = 1/3$, and equation (6) reduces to

$$\ln(E_w/E_0)_2 = w_c[(\overline{CI}) - 1] - (\overline{CI})w \quad (7)$$

The mean cooperative index $(\overline{CI})$ can be calculated from rheological data, but an *a priori* value was obtained from Starkweather's analysis[3] of the cluster behaviour of water adsorbed on polymers, using Zimm's thermodynamic concepts[4,5], as well as calculations by Némethy and Scheraga[6] for water at room temperature and found, for cellulose and Nylon 66, to be: $(\overline{CI}) = 6.71$.

Comparison of data in the literature on the dependence of E_w on w for paper[7-11] gives the mean for $(\overline{CI})$ as 6.70 ± 0.89 The mean w_c for these experiments was 0.047 ± 0.011, whereas w_m for paper is normally between 0.04 and 0.06. The average for different cellulosics studied by Meredith[12] (ramie, Fortisan, viscose rayon and mercerised cotton) was found to be $(\overline{CI}) = 7.7 \pm 2.7$. The value for w_c was indeterminate because of the large standard deviations in the data, (-0.042 ± 0.09). The average for Nylon 66 studied by Meredith[12] and others[13,14] was $(\overline{CI}) = 6.70 \pm 2.1$. The average w_c was indeterminate but clearly < 0.01 g H_2O/g solid $(0.003 \pm 0.005$; W for Nylon 66 is 0.1593).

Thus, the cooperative dissociation of H bonds in mode II is still 'unimolecular' in N, even though approximately seven bonds are triggered to break down together on average.

In mode III, controlling stress relaxation under constant strain, the dissociation is polymolecular in N. This may be explained by imagining the need for a minimum number of bonds, α, having to dissociate simultaneously before a unit jump leading to stress relaxation becomes possible. Thus, it was found empirically from analysis of rheological data[1]

$$\frac{d(N_t/N_0)}{dt} = -\sum_{i=1}^{i=\prime} k_i (N_t/N_0)^{\alpha_i} \quad (8)$$

(where $N_0 = N$ at $t = 0$) with explicit interconnections between k_i with k_{i+1} and α_i with α_{i+1} respectively. The infinite series of different reaction rate constants k_i and cooperative indices α_i soon degenerate into a single reaction of rate k_1 and of order α_1, the 'principal cooperative index', which controls the stress relaxation curve for all values of $(N_t/N_0) \lesssim 0.8$.

Analyses of data published by Houghton and Sellen[15] on dry and wet regenerated cellulose at subzero temperatures reveal interesting maxima and minima in α_1 at particular temperatures.

Thus, in mode III the cooperative dissociation of H bonds is different from that in mode II in being truly polymolecular whereas in mode II it is unimolecular in N.

Details of these studies will be published elsewhere[16].

Cumulative deformation of magnesium oxide crystals by softer sliders

MECHANISMS postulated for the wear of hard crystalline surfaces by softer solids include thermal degradation[1], diffusion and solution[2]; and self abrasion of the harder solid when its wear debris is picked up by the softer surface[3]. A mechanism based purely on mechanical aspects has not yet been established but there has been the suggestion of an 'incubation period' during which the structure of the hard solid has been modified before the onset of visible wear[4]. In earlier publications[5,6], we have established that a dislocated zone was formed in some hard crystals by a softer slider, whenever the pressure between the contacting surfaces was greater than a certain threshold value which was thought to be related to the critical resolved shear stress. For a given load, and in these conditions, the depth of this zone was independent of the slider hardness—regardless of whether the point itself was blunted or visible macroscopic deformation and penetration of the harder crystal was obtained. Then, the depth of the dislocated zone was determined only by the magnitude of the applied load. There were two principal objectives to this particular study. First, to measure the effect of slider hardness on the number of traversals necessary to initiate visible fragmentation and wear in the harder crystal. Second, to use dislocation etching and microhardness techniques to follow the deformation of the harder crystal during the microdeformation preceding fracture—the incubation period.

c
Fig. 1 Illustrating the degree of work hardening, as the tip of the slider was blunted, during the initial traversals on MgO, for △, EN 58J; ○, 95/5 phosphor bronze; ×, 70/30 brass.

The apparatus used has been described in detail elsewhere and only brief experimental details will be given here. All the following results are based on experiments using magnesium oxide as the hard crystal with conical sliders, having included angles of $136°$ at the start of the experiment, made from polycrystalline alloys. The alloys selected for this purpose included an austenitic stainless steel (EN 58J), an α brass (70/30), and a phosphor bronze (95/5). Experiments were carried out at room temperature, using reciprocating sliding at a speed of 3×10^{-4} m s^{-1}, and the surfaces were continuously lubricated with soluble or mineral oils. The direction of sliding was aligned with $\langle 100 \rangle$ crystallographic directions on the chemically polished (001) plane of MgO and the length of the resultant wear track was ~ 0.01 m. Normal loads of 0.5, 1 or 2 kg were used.

The first few traversals caused a flattening of the tip on the metallic slider with a corresponding increase in hardness from conventional work-hardening processes. This effect is reflected in microhardness measurements on the blunted tip, using a Knoop indentor with a normal load of 100 g, as a function of the number of traversals (Fig. 1). The hardness of the slider tended to a constant value, presumably indicating the ultimate level of work hardening for that particular material, within the first ten cycles. There was no visible damage on the MgO surface after the first traversal but dislocations in the contact zone, induced by the sliding, were revealed by etching (Fig. 2a). Subsequent traversals produced slip lines on the MgO surface—typically within the first ten cycles (Fig. 2b). Eventually, a visible crack was formed and then was immediately followed by significant fragmentation (Fig. 2c). The crack pattern was of the chevron form, characteristic of rocksalt crystals, produced by fracture on {110} and {100} planes[7]. The number of traversals to cause the initiation of the first crack, and thus fragmentation, was related to the ultimate hardness of the slider material. The harder the slider, the fewer the number of traversals (N_c) required to produce a crack.

Fig. 2 Stages in the deformation produced by a lubricated slider, under a normal load of 500 g, making traversals in a [100] direction on the (001) plane of MgO. a, Etch pits revealing dislocations after first traversal, ($\times 160$). b, Slip lines visible after ten traversals. ($\times 160$). c, Fragmentation and wear marking the end of the experiment at $N_c = 15,000$. ($\times 24$).

A plot of the ultimate hardness of the slider (H_s) against the critical number of traversals to fracture (N_c) gives a curve which resembles that of an S:N curve based on conventional fatigue data (Fig. 3) in which the maximum stress applied by the slider in each traversal is directly related to the hardness of the slider material. It is important to note, in this context, that the critical number of cycles was independent of the normal load for a given slider. Also, that directly comparable results were obtained with a mineral oil and a water-soluble lubricant. Thus it would appear that this particular change in environment is not important in the wear mechanism. Further support for a mechanism based on fatigue criteria was given by an experiment in which an MgO surface was abraded with a brass for ~ 12,000 cycles—that is, well after maximum work hardening of slider and crystal but before the onset of fragmentation and wear. Subsequently, the top 5 μm of the dislocated zone, which penetrated the crystal to a total depth of 150 μm, was removed by chemical polishing. Sliding was then continued, along the same track, and a further 15,000 traversals were required to produce fragmentation and wear. This compared with $N_c = 15,000$ for the original, undeformed, surface. Note that each point on the curve in Fig. 3 represents the average of at least six measurements, all within a range of 10%.

The coefficient of friction (μ) was measured throughout the experiments for all three types of slider. Where the lubricant became ineffective, adhesion caused a marked increase in friction and fragmentation was immediately observed. Results from such experiments have not been included in Fig. 3. In the normal case, μ decreased during the initial mutual work hardening of slider and crystal but then remained constant until the onset of fragmentation. At this point, an immediate and significant increase in friction was observed. It can, however, be concluded that fragmentation was responsible for the increased friction and not vice versa.

Examination of the abraded MgO surface, using dislocation etch pit techniques and microhardness measurements, confirmed some of the earlier observations made on the basis of a single
Fig. 3 The H_s:N_c curve for a (001) MgO surface abraded in the [100] direction. Note a limiting slider hardness of ~ 2.25 GN m^{-2}.

indentation or traversal[5] and gave further information on the nature of the incubation period. The depth of the resultant dislocated volume was determined not by the shape or hardness of the slider but only by the magnitude of the applied load. Dislocations produced by repeated traversals were generally contained within the dislocated volume established by the first traversal. Thus the dislocated volume remained constant whilst the dislocation density increased during the first hundred traversals. Furthermore, microhardness measurements show that the increase in dislocation density causes work hardening both on the surface and within the bulk of the magnesium oxide. Typical values, using a Knoop indenter aligned in a [110] direction on the (001) MgO surface with a load of 100 g, are shown in Fig. 4 for all three slider materials. It would seem that
Fig. 4 Hardening of the MgO surface, by traversals on the (001) plane in a [100] direction, was shown to be dependent on the ultimate hardness of the slider material. △, EN 58J; ○, 95/5 phosphor bronze; ×, 70/30 brass.

the degree of work hardening in the MgO is again related to the ultimate hardness of the slider material. Results obtained by removing the surface layers, using chemical polishing techniques, and indenting on the newly exposed surfaces in the same manner reveal the hardening in depth below the original surface (Fig. 5).
Fig. 5 Bulk hardening of the MgO crystal after ~ 200 traversals of brass slider under a load of 500 g.

In summary, these experiments provide a method of identifying the range of slider hardness within which fragmentation and wear of a harder crystal can be anticipated. Also, we now have the possibility of establishing a limiting slider hardness, akin to a fatigue or endurance limit, below which fragmentation of a given solid will not take place in a given lifetime. For example, MgO with a hardness of 9.8 GN m^{-2} should have a reasonable lifetime, in abrasive conditions, provided the hardness of the softer material does not exceed 2.25 GN m^{-2}. Current work has established that the behaviour of various other non-metallic crystals is comparable with MgO and similar H_s:N_c curves have been obtained. Clearly this information is of technological interest wherever a soft material abrades a harder one—as in gemmological applications and metal cutting operations.

Feathering and flight evolution in *Archaeopteryx*

WITH the description of further specimens[1,2] there has been a resurgence of interest in *Archaeopteryx*. Although there is no final agreement on whether it was mainly arboreal or terrestrial, recent opinion[3] seems to favour the latter. There has been discussion on its reptile origins[4–6] and on its ability to fly and the general problem of the evolution of powered flight[3,7–12]. However, most of these studies have been made by specialists who are not ornithologists and who usually tend to extrapolate from reptile forms and behaviour in their discussions. Whatever its precursors, *Archaeopteryx* is regarded as a bird and to interpret adequately such evidence as we have we must consider it in relation to what we know of birds as well as reptiles.

Archaeopteryx possessed structures very closely resembling the flight feathers of Recent birds, which should confer an advantage by supporting it during movement, while body feathers, if present, would aid thermoregulation; but feathers also have disadvantages in being fragile and subject to abrasion. In Recent birds this is partly overcome by regular moult and replacement, but we do not know if *Archaeopteryx* had a moult. Recent birds also avoid feather damage by postures and movements in which the plumage does not usually rub or strike against surrounding objects, the larger feathers of wings and tail usually being held clear of the substrate. The possession of feathers by *Archaeopteryx*, even were it a reptile, should therefore impose some limitations on both posture and movement, comparable with those of Recent birds; and these limitations would be likely to have modified some of its characters already, and to affect its subsequent evolution.

Feathers probably evolved before avian flight and Ostrom[3] has suggested that the large feathers of the forelimbs were originally produced for a different purpose. He regards the digits as functional in catching small live prey and suggests that the feather may have formed a large area of catchment for trapping small creatures such as insects. It is possible to envisage an earlier and shorter form of feathers being spread like small nets and slapped down over insects to aid capture, but I would suggest that the feathers on *Archaeopteryx* had developed beyond this stage and that to use them for such a purpose would be likely to damage and destroy them, while the total size of the spread wing would tend to hinder the use of the forelimbs for rapid movements in catching prey.

It cannot be argued that the similar large feathers along either side of the tail were used for capturing prey, and in view of their position it is reasonable to suppose that their function was for support during movement. It is also likely that the extensive feathering of the forelimbs had a support function at this stage in evolution, and while Ostrom[6,12] argues that the skeletal structure precludes an ability to fly in the true sense, there seems to be no objection to the idea that the feathers of forelimbs and tail might be used to prolong the passage through the air of an individual that had leaped from some eminence, whether by gliding or by some crude flapping flight.

The feathering should affect both normal movement and the subsequent evolution of flight. Some earlier reconstructions of *Archaeopteryx* and theoretical proavian forms based on Recent reptiles[13,14] assumed that *Archaeopteryx* climbed trees by using the well developed digits, and launched itself into the air from a height; with flight evolving through a stage of gliding down from high perches. The feathering of *Archaeopteryx* is developed to a degree that makes it most improbable that it would climb in a lizard-like fashion or clamber among twigs using all four limbs as some reconstructions suggest. Any arboreal movement is likely to have been limited to perching, running along branches and leaping between them, meanwhile probably using the wings for balance and aerial support.

In his recent papers Ostrom[3,6,12] describes *Archaeopteryx* as a cursorial, and presumably terrestrial predator. This would accord with the above comments but would not explain why powered flight should have evolved in such circumstances. He believes the flight of *Archaeopteryx* to have been "flapping leaps" to capture insect prey, and presumably envisages flight evolving as an aid to predation. In Recent birds, flight as a means of catching prey appears to be a secondary adaptation, for species which use it, from simple flycatchers to the more elaborate aerial feeders, have additional structural modifications for this purpose, and in its earlier stages flight would have had the greatest value as a means of escape from predators. Driver and Humphries[15] in their studies of protean behaviour have shown that an element of unpredictability in the behaviour of a prey species will help it to evade capture. If prey which has previously moved along the ground suddenly launches itself into the air in a long leap, leap and glide, or full flight, a terrestrial predator is temporarily baffled and likely to discontinue the hunt. This is a very effective anti-predator device, a fact reflected in the evolution of such behaviour in a number of different groups of animals. Anyone who has tried to catch an almost-fledged nestling or a slightly injured adult bird without the powers of sustained flight will be aware of the way in which even brief bursts of short flight by the prey can make capture difficult for a relatively sophisticated predator such as man.

We can envisage *Archaeopteryx* as a bird-like creature probably resembling the coucals, *Centropus* spp., which are similar in general proportions with rather weak rounded wings, long tails and well developed legs. These latter birds are mainly terrestrial or semi-arboreal, walking or running through low vegetation or travelling through shrubs and low trees, moving along branches and jumping from branch to branch. They fly with reluctance but if hard-pressed will ascend to a higher perch and then take off in a weak and frantic flight, travelling a little distance before dropping into low vegetation and disappearing.

Archaeopteryx could have moved in similar fashion, and if launching itself from some eminence enabled it to escape terrestrial predators, there would have been a selective advantage in a readiness to take flight. If the ability to move through the air was poor and likely to result in a landing too close to the point of take-off there could be a likelihood of rediscovery during random searching by the predator. There would therefore be additional selection pressure in favour of individuals that could travel further through the air before landing. It can be argued that factors such as these could provide pressures for the evolution of powered flight in a mainly terrestrial animal without the need for an ability to climb in the strict sense or for the modification of specialised predatory leaps.

Regarding *Archaeopteryx* as a bird is therefore useful in predicting the likely limitations implied by the possession of feathers, and the probable advantages of even brief periods of movement in the air. It may prove helpful in interpretating other aspects of this important evolutionary link.

Intake and digestion of hill-land vegetation by the red deer and the sheep

DOMESTICATED sheep and feral red deer (*Cervus elaphus*) are the two principal producers of food for human consumption from a large proportion of the rough grazings of Scotland. There is considerable interest in the possibility of increasing the production of venison by farming the red deer, and studies of the degree of domestication required, the development of biologically sound management practices and their economic viability are in progress[1]. A fundamental question is whether the red deer can utilise the indigenous vegetation found on the hills more efficiently than does the sheep, and, if so, to what extent this is brought about by its greater ability to range over and graze selectively on hill vegetation or by its ability to consume and digest more of the poor quality vegetation. We have investigated this latter aspect and now report that on such diets red deer consume greater quantities of digestible dry matter per unit metabolic body weight than sheep. The greater ability of the deer to increase voluntary food intake during the summer months is also discussed.

For this study we used 12 castrated male red deer and 12 castrated male Scottish Blackface sheep, aged 18 months. Both species were treated in a similar manner from 6 months of age and were accustomed to being housed in metabolism pens before being given diets of common heather (*Calluna vulgaris*, L. Hull) and *Agrostis/Festuca* grass heath (two of the common types of hill vegetation grazed by both species). In two experiments carried out in January and April 1976, the animals were offered, *ad libitum*, freeze-stored vegetation which had been harvested mechanically in the autumn and which was known to provide a diet similar to that selected by grazing during the winter (unpublished data of J.A.M.). Measurements were made of the voluntary food intake (VFI) and digestibility of each diet. The particulate-phase marker, [103]Ru-phenanthroline[2], was used to estimate the mean retention time[3] (MRT) of digesta between the rumen and the faeces—an index of the time undigested food particles spend in the gastrointestinal tract. Results are given in Table 1.

In both January and April the red deer ate at least twice as much heather and *Agrostis/Festuca* as the sheep. Surprisingly, on the heather diet the deer were able to digest their higher intake to the same extent as the sheep (Table 1), but with the *Agrostis/Festuca* diet they showed a more predictable fall in digestibility (7–8 percentage units). On both diets MRT was considerably shorter for the deer than the sheep. It is not possible to assess to what extent these differences were due to the different intakes of the two species, but further experiments have shown that when the same animals consumed similar quantities of a higher quality ration (dried grass pellets), the MRT in the red deer was still significantly ($P < 0.001$) shorter than in the sheep (unpublished). This latter result is in agreement with earlier studies using chopped dried grass and grass hay diets[4,5] which suggest a real between-species difference in the speed at which digesta passes through the digestive tract.

The VFIs of both the red deer and the sheep were higher in April than in January. In the sheep, the 40% increase in VFI of heather in April was accompanied by a reduction in the digestibility of the diet and in MRT. This result is in agreement with relationships between VFI, digestibility and MRT previously found in sheep and cattle and which support the generally accepted hypothesis that with medium-quality long roughage diets, the control of VFI in sheep is related mainly to the filling effect in the digestive tract, particularly in the rumen, and to the rate of removal of food residues from that organ[6].

In contrast, the large increase in VFI of deer of 70% between January and April, which has been associated with changes in daylength[7], was not accompanied by any change in digestibility or MRT. This suggests that the amount of feed residues transferred per unit time down the gastro-intestinal tract of the red deer was higher in April than in January. The hypothesis that VFI of long roughages is controlled by the filling effect in the digestive tract can only hold for the deer at both times of the year if the volume or capacity of their digestive tract, or at least some section of it, had increased considerably. Although the mechanisms whereby this may occur are not known, it is likely that they are under some form of hormonal control related to daylength.

In spite of these seasonal differences in VFI the red deer ate twice as much digestible dry matter as the sheep on both kinds of hill vegetation. This suggests that red deer are better adapted than sheep to grazing hill vegetation in winter and spring, providing that both species exhibit similar grazing behaviour, have similar maintenance requirements per unit of metabolic liveweight, and have similar rates of production and utilisation of the end products of digestion. These latter aspects are being investigated further.

Superposition images are formed by reflection in the eyes of some oceanic decapod crustacea

LIKE moths, the eyes of many pelagic and bottom-living decapods appear to glow brightly when viewed from the direction of illumination[1]. It has generally been assumed that the optical system involved is similar to that in nocturnal insects, that is, the superposition mechanism of Exner[2]. The essential feature of Exner's theory is that the optical apparatus of the cornea and crystalline cone refracts light through twice the angle at which it was incident on the cornea (Fig. 1a). Light from many facets then combines to form a single image on the receptor layer, and if this is backed by a tapetum the light is reflected out through the same facets that it entered, causing the glow. There is now no doubt that Exner's mechanism is present in some insects[3]. Recent accounts have, however, cast doubt on whether it occurs in crustacea[4,5]. This is largely because the high refractive indices and inhomogeneities required of the optical components have been shown not to be present. In this paper I show that superposition images are formed in the eyes of a midwater shrimp, but in a different manner (Fig. 1b).

Live *Oplophorus spinosus* (Coutière), about 5 cm long, were obtained from trawls at a depth of 500 m in the North Atlantic during a recent cruise of the RRS Discovery (July–August 1976). The eyes are almost spherical, and when illuminated they exhibit a bright orange glow over a circular area whose diameter (905 μm) is slightly more than half the diameter of the eye itself (1,580 μm). The glow does not disappear on exposure to light, indicating the absence of occlusory distal pigment such as is found in moths[6]. After fixation for 1 h in a mixture of glutaraldehyde and formalin in cacodylate-buffered seawater, which stiffens the tissues without loss of transparency, an eye was cut in half, and the layout of the component parts is shown in Fig. 2b. As in insect superposition eyes, the rhabdom layer has a radius of curvature approximately equal to half that of the eye surface.

A superposition image was clearly visible when the half eye was illuminated by a small source (a light guide) at a distance of 10 cm. This produced a single small but somewhat diffuse spot of light which moved around the rhabdom layer in the same direction as the source—that is, the image was erect. Occluding different parts of the cornea showed that light contributing to the image entered the eye over approximately half its diameter. When two sources were used distinct images were observed, provided the sources were separated by 15° or more at the eye.
Dissection of unfixed material failed to reveal any 'crystalline' cones, although clear gelatinous material was present in the spaces in the distal pigment region, and also in the 'clear zone' between this and the rhabdoms. This is in marked contrast to the situation in, for example, euphausiid eyes where hard highly refractile cones are present as a layer beneath the cornea. The corneal facets themselves have negligible focusing properties. After fixation the gelatinous material stiffened into recognisable square-sided tapering structures (Fig. 2b) which could be easily separated from each other. Each of these consisted of a short non-pigmented outer section, a second more refractile segment extending to a depth of 150 μm from the eye surface, and lined with pigment for the proximal two-thirds of its length, and a long tapering tail whose tip lay 280–300 μm deep, in the layer of cell bodies immediately above the rhabdoms. An estimate of the refractive indices of the parts of fixed cones was made by finding cones lying with their side faces at 45° to the microscope slide, and measuring the prismatic bending of parallel rays passing through them. The distal region gave a deviation of 5.9°, corresponding to a refractive index of 1.41, and the proximal tail gave 3.3° or an index of 1.37. These values are quite in keeping with the consistency of the material, and are far too low to be compatible with image formation by refraction, using curved surfaces or lens–cylinder optics. (Euphausiid cones, treated similarly, gave a refractive index of 1.54.)

Teasing fresh material from the distal region showed that the cones are separated from each other by two kinds of pigment: a layer of reflecting material which lines the four faces of each cone and has a green specular appearance at near normal incidence, and behind this a brown pigment which fills the gap between the cones. Optically, therefore, each cone can be thought of as a silvered, four-sided prism.

This observation leads directly to the hypothesis of image formation outlined in Figs 1b and 2a. Parallel light reaching the eye is reflected at one of the faces of each cone and is bent through an angle approximately equal to twice the angle of incidence at the eye, just as in a refracting superposition eye (Fig. 1). The angle is in fact slightly greater than this, because of the 8° taper of the cones. A consequence of this is that many facets will redirect light to an approximate focus on the surface of a sphere concentric with the eye, and with slightly more than half its radius of curvature. The limiting ray will be the one that just manages to enter and emerge from a reflecting prism (left-hand ray, Fig. 2), and this makes an angle of 60° with the eye surface. This will also be the ray which emerges nearest the edge of the patch of 'glow' and it will be located approximately half way out from the centre of the eye. It can be seen from Fig. 2a that some light will tend to pass straight through the aperture of the central cones without being reflected (dashed lines). The fate of this light is uncertain: some will certainly be totally internally reflected by the walls of the tails of the cones (angles of incidence more than the critical angle, 77°) and the image is not likely to be greatly spoiled.

Two other features of the glow tend to confirm the hypothesis just given. Towards the edges of the glow patch light from individual facets is unevenly distributed, each showing a dark band which gets wider and finally occludes the facet completely. This 'venetian blind' effect is simply explained by the progressive restriction in the width of the slit of light that can enter and emerge from each reflecting prism (Fig. 2a). Secondly, the colour of the glow changes from yellow/orange in the centre (that of the bleached rhabdoms) to green at the edge of the patch. If, as seems likely, the mirror surface is due to thin-film interference[7], one would expect that all wavelengths would be reflected at high angles of incidence (near the centre), but that the light would take on progressively the interference colour of the

Fig. 1 Superposition image formation (*a*) by refraction (modified from Exner) and (*b*) by reflection.

Fig. 1 Superposition image formation (*a*) by refraction (modified from Exner) and (*b*) by reflection.

Fig. 2 Optical (*a*) and anatomical structure (*b*) of part of the eye of the shrimp *Oplophorus*. In *a* it is assumed that the only optical components in the eye are the reflector-lined faces of the cones. Solid lines show how reflected light is brought to a focus, and dashed lines indicate pencils of rays that pass through directly. The figure was constructed as accurately as possible from measurements made on fresh or recently fixed eyes. The numerals on the left show depths of each layer from the surface. *b* shows the parts of the eye as visible in a hemisected eye seen through a dissecting microscope.
reflecting material itself at lower incident angles. Where this angle reaches 60°, at the edge, the green colour observed is similar to that of the reflecting material observed directly.

It is concluded that reflection in the cones provides an adequate explanation of the images observed, and that a refraction mechanism is not present. Since this paper was first submitted, I have learned from Professor K. Kirschfeld (Tübingen) that exactly the same optical arrangement as that given here has already been proposed independently by Klaus Vogt (Stuttgart) to account for image formation in the eyes of freshwater crayfish[8], which also exhibit a 'glow' when dark adapted[9]. His note was published last year. It also turns out that the theoretical possibility of imagery of this kind was in fact dismissed by Exner in this 1891 monograph, and the discovery of this mechanism as a practical reality properly belongs to Vogt. His paper and mine leave little doubt that this is the standard method of superposition image formation in decapod crustacea.

I thank Dr Peter Herring for making possible my participation in the Discovery cruise, Professor Eric Denton for critically reading the manuscript, and Dr Adam Locket for help with suitable fixatives. Financial assistance is acknowledged from the SRC and the Royal Society.

Frequency-dependent selection at two enzyme loci in *Drosophila melanogaster*

RECENT development in population genetics indicate that it is often misleading to treat selective values as constants[1-5]. These studies indicate that selective forces may be a function of genotype frequencies (frequency-dependent selection).

For example, if the rarest genotype is most fit then the rare allele will increase in frequency but will not become fixed in the population, because as it gets more common the fitness of its carriers decreases. This mechanism is attractive since it leads to a stable gene frequency equilibrium which may not involve problems of genetic load or inbreeding depression. Experimental evidence has been obtained[6,7] which supports the view that frequency dependence is involved in the maintenance of the esterase-6 (*Est-6*) and alcohol dehydrogenase (*Adh*) loci in *Drosophila melanogaster*. However, these results are subject to two major criticisms[8-11]. First, the observed frequency dependence may have resulted from poor experimental design. In the original report[6] fitness estimates were made by comparisons of adult frequencies with those expected from the gene frequencies in the previous generation. Frequency-dependent selection appears as an artefact of this method[12]. Second, since inbred lines were used in these studies problems of linkage disequilibrium may have occurred. If this view is correct then the observed selective differences were due to differences between lines, not to differences between alleles at a locus. As a consequence of these criticisms the role of frequency dependence as a force responsible for maintaining enzyme polymorphism has been disputed[9]. The experiments reported here overcome these criticisms and indicate that frequency-dependent selection should be reconsidered as an important mechanism involved in the maintenance of enzyme polymorphism.

From the Kaduna population, two pairs of lines were derived. One pair were segregating at the *Adh* locus while homozygous at the *Est-6* locus for the *F* and *S* alleles respectively whereas the other pair were homozygous at *Adh* and segregating at *Est-6*. Each line was derived independently as the progeny of 30 pairs of homozygous parents sampled from the population. The lines had been kept in population cages (as large populations) for approximately 18 months before the experiments were carried out. For each experiment 200 newly-emerged larvae (0–3 h old) were competed. They were put in a 10×4-cm *Drosophila* vial containing 10 ml of the following medium : maize meal, 26.25 g; molasses, 26.25 g; agar, 10 g; flaked brewers yeast, 2.5 g; nipagin, 2.5 g; propionic acid, 2.5 ml; water, 1,000 ml. The frequency of the *F* allele in the experimental vials was altered by changing its relative proportion in the larval mixture (for example, a vial with $P_f = 0.15$ would contain 30 *FF* homozygotes and 170 *SS* homozygotes). For the *Est-6* experiment seven frequencies of the *F* allele were used ($P_f = 0.15$; 0.25; 0.40; 0.50; 0.60; 0.75; 0.85) and for the *Adh*

Table 1 The relative viabilities of *FF* and *SS* flies when grown at different frequencies

Enzyme locus	P_f	FF input*	SS input*	FF survived (%)	SS survived (%)	Total survived (%)
	0.15	120	680	55.8	34.0	37.3
	0.25	200	600	46.5	38.0	40.1
	0.40	320	480	40.9	46.9	44.5
Est-6	0.50	400	400	38.8	43.0	40.9
	0.60	480	320	27.1	46.9	35.0
	0.75	600	200	38.0	57.0	42.8
	0.85	680	120	33.2	68.3	38.5
	0.15	120	680	65.8	45.7	48.8
Adh	0.50	400	400	43.8	35.3	39.5
	0.85	680	120	53.4	52.5	53.3

*Each result is the sum of four pooled replicates.

experiments three frequencies of the *F* allele were used ($P_f = 0.15$; 0.50; 0.85).

The genotypes of all emerging flies were determined by the methods of O'Brien and MacIntyre (*Est-6*)[13] or Day *et al.* (*Adh*)[14]. The results are shown in Table 1.

The results have been analysed by the heterogeneity χ^2 method (Table 2). The regression of the difference in survival between *FF* and *SS* flies on frequency is significant for both the *Est-6* and *Adh* experiments (*Est-6*, $P<0.005$; *Adh*, $P<0.01$). These results clearly demonstrate frequency dependence operating at both the *Est-6* and *Adh* loci. For the *Est-6* locus at *F* frequencies less than about 30% more *FF* flies survive than *SS* flies. This situation is reversed at frequencies above about 40% *F*. Here it would seem that a frequency-dependent mechanism is sufficient to maintain the polymorphism, at least in these culture conditions. This is not the case for the *Adh* polymorphism since more *FF* flies survive than *SS* flies at each frequency. The results for the *Adh* polymorphism differ from those of Kojima and Tobari[7] since these authors presented data which showed that the relative advantage of the *F* allele changed to a disadvantage as its frequency increased. My results have been confirmed by Briscoe[15] who used the same materials but different experimental methods. In a further communication (Morgan, in preparation) I will present data that indicates that the degree of frequency dependence at the *Adh* locus can be modified by growing flies on different culture media.

The results presented in this paper suggest that the role of frequency dependence in maintaining enzyme polymorphism should be examined in greater detail.

Table 2 Heterogeneity χ^2 of the differences in survival between *FF* and *SS* flies grown at different frequencies*

Est-6	d.f.	χ^2
Average difference in survival between *FF* and *SS*	1	29.66*
Linear regression of $S_f - S_s$ on P_f	1	99.00*
Departure from linearity	5	9.25†
Replicates	21	23.74†
Adh		
Average difference	1	14.86*
Linear regression	1	7.54‡
Departure from linearity	1	0.17†
Replicates	9	4.15†

For each trial, differences in survival between the two genotypes may be tested as χ^2_1, which equals $nP_f (1 - P_f) (_fS - S_s)^2/S(1 - S)$, where *n* is the total number of individuals at risk, P_f is the starting frequency of *FF* flies and S_f, S_s and S respectively are the proportions of *FF*, *SS* and all flies which survive. Over a set of trials, the sum of these values may be partitioned as in the table.
*$P < 0.005$.
†No significant difference: $P > 0.05$.
‡$P < 0.01$.

X-ray induced mutations, DNA and target theory

THAT X-ray induced, specific locus, germ-line mutation rates vary significantly in eukaryotes is generally known, but the factors that are responsible for such differences have not been assessed in detail. It was recently proposed[1] for a variety of species that mutability is closely and simply related to total DNA per genome. This approach, however, has not stood the test of critical review[2]; in fact, even within one species (mouse) there are major differences between the rates for different genes, and even for different germ cells[3–5]. I have therefore taken a different approach by considering the radiobiology of the individual gene. The analysis leads to three major conclusions. (1) Mutation rates tend to be much lower than radiation theory predicts. (2) Selection and/or repair are major factors that determine the rates. (3) The mouse 7-locus test, which provides a principal data base for the standards of human radiation hygiene, may not provide adequate overall representation of the mutability of the mammalian genome, so more research is needed.

Before considering the differences in rate between organisms, it is of interest to examine the differences between genes that are irradiated in the same germ cell of a particular organism. As an elementary step, consider the following analysis that is based on classical target theory. The fundamental premise is that bigger genes (molecules) are more likely to be hit than smaller ones and therefore should be more mutable. The calculation of target size involves the relation between observed hits and the distribution of ion pairs generated in the exposed material by the absorbed radiation, and has been applied to the study of enzymes and viruses[6,7].

In the usual germ-line mutation experiment, a parent is irradiated and the F_1 progeny are screened for the mutant phenotype. The mutation rate of a particular gene is calculated as mutations per rad per generation where per generation indicates that the observations were made on the viable progeny. But the frequency of observed hits (mutants) in these progeny is unlikely to be equal to the frequency of hits (mutations) in the parental germ cell since: (1) some hits will be repaired; (2) some hits will be carried in cells that die out or are selected against; (3) some hits will induce trivial mutations, that is, the mutation does not induce a significant change in phenotype although

provided adequate opportunity to do so. These "deflating" factors will tend to make the target-theory estimate of gene size too small.

There are also "inflating" factors that tend to make the estimate too large. First, in addition to direct hits, free radicals generated in nearby molecules (for example water) may mutate the target gene. Secondly, since "target" is an operational term, its volume might in fact represent the aggregate volume of several separate genes, any one of which when hit can directly or indirectly induce the mutant phenotype.

It is clear that the estimate of gene size by target theory will probably be incorrect, depending on the magnitude and balance of a number of factors. Nonetheless, such an incorrect estimate can be useful for purposes of comparison. As the standard for such comparison, we use the molecular weight of a typical gene. Since each codon has a molecular weight of about 2,000, a gene that determines a protein of 200 amino acids has a molecular weight of about 400,000.

I applied target theory to the data of the three tests with mouse spermatogonia (250-kV X rays, 60–90 rad min^{-1}), using the method outlined by Lea (chapter 3, fig. 9 of ref. 6). The method is adequate for the comparisons to be made here, although it does not provide a full treatment of the problem[8–10].

The 7-locus test used one cartilage and six coat-colour genes. For a dose of 300 rad, the mean probability K of inducing a mutation was 2.7×10^{-7} per gene per rad per generation[4]. Greater doses or lower dose rates reduced the probability. The mean dose per mutation (Lea's 37% dose) is therefore taken as $1/K = 3.7 \times 10^{6}$ rad, for which the associated molecular weight is 360,000 (180 codons). The close agreement of this estimate with that based on the model is presumably fortuitous. Nonetheless, the fact that there is numerical agreement rather than gross disagreement gives perspective on the balance of deflating and inflating factors.

In a very much smaller set of experiments with an analogous "6-locus test", the value of K was about one-third that of the 7-locus test[11].

In the case of the H-test (30 class I histocompatibility genes)[5], the mean value of K was 1/60 that of the 7-locus test, and the associated molecular weight is therefore about 5,000—an underestimate equivalent to 2.5 codons. The underestimate is informative, however. It indicates that the set of deflating factors is much more important than the inflating ones.

With two such disparate results for the mouse as a point of departure, their generality becomes of interest—will various genes in diverse species behave like the 7-locus group or the H-group? The literature was recently reviewed[2] for X-ray induced, intralocus, forward mutation rates. Determinations were found for *Schizosaccharomyces pombe* and *Saccharomyces cerevisiae* (yeast), *Neurospora crassa* (mould), *Drosophila melanogaster* (fruit fly), *Arabadopsis thaliana* (flowering plant). *Zea mays* (maize) and *Hordeum vulgare* (barley). From the summary, I obtained the distribution of 16 values of K for different genes and different groups of genes. The highest value was 4.7×10^{-8}, equivalent to 25 codons. Eleven fell between 3×10^{-8} and 4×10^{-9}, with a mean of 1.5×10^{-8} (7 codons), and four were below 3×10^{-9} (1 codon).

It seems that the genes or groups of genes tested so far (outside the mouse) tend to react like the mouse H-group rather than the 7-locus group, and that the factors that deflate the mutation rate (per gene per generation) are much more effective than those that inflate it. To what extent this conclusion will continue to be generally true for all types of genes, and especially for mutations other than forward ones, remains to be seen. Meanwhile, the analysis provides some specific orientation towards the general problem and emphasises the need for much more

research, both for genetics *per se* and for radiation hygiene, which relies heavily on the 7-locus test as a data base for setting standards.

Culture of human malaria parasites *Plasmodium falciparum*

MALARIA is a major cause of morbidity and mortality, claiming an estimated one million lives a year in Africa alone[1]. *Plasmodium falciparum*, the most important agent of human malaria, has not been maintained for more than 2–6 d *in vitro*[2–10]. The development of a vaccine for malaria depends on suitable culture methods for the production of relevant antigens[1]. We describe here a new culture method for *P. falciparum*, which involves an inoculum of cryopreserved parasites and make possible an analysis of merozoite–erythrocyte interactions, growth for more than 3 weeks *in vitro* and the collection of merozoites. Merozoites are of particular interest because vaccination with the merozoites of *P. knowlesi* protects rhesus monkeys from infection with this species of malaria parasite[11].

Parasites for culture were obtained from a splenectomised chimpanzee (*Pan troglodytes*) inoculated with a chimpanzee-adapted isolate of the Malayan Camp strain of *P. falciparum*[12]. Nine days after inoculation 52% of its erythrocytes were parasitised with ring forms and 6% with schizonts. A sample (50 ml) of this infected blood was collected in 500 U of heparin and cryopreserved in 60 aliquots by the method of Diggs *et al.*[3].

Growth of *P. falciparum* in erythrocytes from five species was tested. Blood was drawn in heparin from human volunteers, owl monkeys (*Aotus trivirgatus griseimembra*), rhesus monkeys (*Macaca mulatta*), Hartley guinea pigs (*Cavia porcellus*) and also from the chimpanzee which had been infected (and then cured with mefloquine[13]). These erythrocytes were separated from plasma and leukocytes, mixed with an inoculum of thawed parasitised chimpanzee erythrocytes, and the mixture was cultured at a low oxygen tension in modified tissue culture medium 199. Samples were taken at the times indicated, thin smears were made and stained with Giemsa and 1,000 erythrocytes were examined for parasites. A representative experiment is presented in Table 1. Erythrocytes from humans and the chimpanzee, both of which can be infected *in vivo* with the Camp strain of *P. falciparum*, were parasitised *in vitro*. Erythrocytes from rhesus monkeys and guinea pigs, which cannot be infected *in vivo*, were not invaded to a significant extent *in vitro*. Other experiments provided evidence that erythrocytes from owl monkeys (which can be infected *in vivo*) support growth *in vitro*; too few experiments have

Table 1 Malaria grown in four species of erythrocytes

Test erythrocytes	Trophozoites at 24 h	Trophozoites at 72 h	Ratio of 72 h to 24 h
Human	3.7±1.5	23.0±3.1	6.2
Chimpanzee	5.3±0.9	33.3±1.7	6.3
Rhesus	3.0±1.2	1.3±0.3	0.4
Guinea pig	5.5±2.5	1.8±0.5	0.3

Numbers of trophozoites are given per 1,000 erythrocytes (mean ± s.e. of triplicate cultures).

Test erythrocytes and thawed[3] chimpanzee erythrocytes (50% parasitised with ring forms; schizonts did not survive thawing) were mixed at a ratio of 25 : 1 and cultured at a final concentration of 5×10^7 per ml in an atmosphere of 3% CO_2, 6.6% O_2, balance nitrogen at 37 °C (3 ml per 5-cm^2 flask, or 0.2 ml per microtitre well). Culture medium 199 (with Earle's modified salts) was enriched with glucose (2 mg ml^{-1}), 2 mM glutamine, 3×10^{-5} M 2-mercaptoethanol, (±)-α-tocopherol (emulsified) (30 µg ml^{-1}), gentamycin (25 µg ml^{-1}), 10% heat-inactivated foetal bovine serum, and 10 mM *N*-Tris-(hydroxymethyl)methyl-2-aminoethanesulphonate (TES) buffer. (One part TES acid to 1.4 parts TES sodium salt gives a *p*H of 7.35 at 37 °C). Leukocytes and plasma had been removed from the erythrocytes by passage through a column of cellulose powder[14] followed by washing the cells several times in media.

been done to comment on the finding[9] that they support growth of *P. falciparum* less well than do human erythrocytes.

In these short term cultures the parasites grow first in the erythrocytes of the chimpanzee inoculum (ring forms predominated at 0 h, more mature trophozoites at 24 h and schizonts at 42 h); then at 48 h merozoites invaded new erythrocytes (young ring forms were also seen at this time in the new erythrocytes). By 72 h the parasite had grown to the trophozoite stage again. At both 48 and 72 h the cultures with human erythrocytes had 15 to 50 times more parasites than cultures with rhesus erythrocytes. Small numbers of degenerating parasites were seen in all cultures. The viability of the cryopreserved parasite inoculum varied from 20 to 50% as judged by the numbers of maturing trophozoites after 24 h of culture.

Long term culture was also possible. Schizonts were concentrated by centrifugation every 2 or 4 d and reinoculated into a culture with new human erythrocytes. The parasite exhibited some asynchrony of growth: on day 22 of culture

Fig. 1 Malaria parasites after 22 d in culture. *a*, Merozoites invading erythrocytes (top right), schizonts (top left and middle), trophozoites (bottom middle); *b*, ring forms; *c*, a gametocyte. Parasites were cultured essentially as described in Table 1, except that every 2 or 4 d the erythrocytes were centrifuged at 400*g*, resuspended in a small volume of medium, centrifuged in capillary tubes at 1,300*g* for 2 min, and the capillaries were scored and broken to collect the upper brown layer of schizonts (usually 3×10^7 cells) which was added to a new 15-ml subculture containing 3×10^8 human erythrocytes in a 22-cm^2 flask. The medium was usually changed every 48 h with the subculture. After the first 4 d of culture, an extra 15 mM TES buffer was added, and 20% autologous human serum replaced the foetal bovine serum in the medium.
Fig. 2 Thawed parasitised chimpanzee erythrocytes (90% parasitised after a centrifugation step in capillary tubes) were cultured without added erythrocytes, but otherwise essentially as described in Table 1. After 44 h, the culture was centrifuged at 400*g* for 8 min. The supernatant was then taken and centrifuged at 1,000*g* for 10 min and the small grey pellet was resuspended, smeared and stained with Giemsa.

schizonts, invading merozoites, ring forms, trophozoites and what appeared to be immature gametocytes were seen (Fig. 1). The total number of schizonts recovered from each subculture was approximately equal to the number added 2 d previously, except on day 22 when twice as many schizonts were recovered. This increased yield followed an increase in the frequency of changing the medium from every other day to every day. A significant metabolic production of acid after 1 d in culture was indicated by the yellow colour of the phenol red in the medium. The addition of a flow system to continually replenish the medium should result in better yields. Further manipulation of culture conditions might also result in the production of mature gametocytes which could be used to study the sexual cycle *in vitro*.

Merozoites were obtained by culturing parasitised erythrocytes to the schizont stage, centrifuging at low speed to remove the unruptured schizonts, and then centrifuging at high speed to pellet the free merozoites (Fig. 2). These *P. falciparum* merozoites have not yet been examined for viability, but are expected to have a lifespan measured in minutes[15].

Experiments to evaluate the importance of the various components of the culture medium are incomplete. Others have reported improved growth of malaria parasites with the use of TES as a buffer[7], the removal of leukocytes[16] and the use of a low oxygen tension[17,18].

As expected from work with *P. knowlesi*[19-21], the growth of *P. falciparum* in various mammalian erythrocytes *in vitro* correlated with the susceptibility of the erythrocyte donors *in vivo*. This erythrocyte specificity apparently resides in the interactions between the erythrocyte and merozoite surfaces, since very few merozoites adherent to erythrocytes were noted at 48 h in cultures containing erythrocytes from non-susceptible species. The few interactions that were noted probably occurred with residual chimpanzee erythrocytes from the inoculum. This culture system is being used to study *P. falciparum* interactions with various human blood group erythrocytes with and without enzyme treatments (L. H. Miller *et al.*, manuscript in preparation), as reported for *P. knowlesi*[20-23].

Further improvements in the culture of *P. falciparum*, in particular the production of large numbers of merozoites, should facilitate biochemical and immunological studies that may lead to an effective vaccine for malaria.

While this manuscript was in preparation, Trager and

Jensen reported the continuous culture of *P. falciparum*[24].

Direct estimation of frequency of cytotoxic T lymphocytes by a modified plaque assay

Thymus-derived lymphocytes (T) have been shown to have a major role in cell-mediated immunity against foreign transplants and syngeneic tumours[1,2]. *In vitro*, several assays have been developed to measure thymus-dependent cell-mediated immunity, making use of the cytotoxic potential of these effector cells[3]. Precise estimates of the number of cytotoxic T lymphocytes (CTL), however, are not possible by available methods. We report here a new method to quantify the CTL present in a mixed cell population. The method is based on the ability of CTL to kill specifically adjacent target cells fixed on monolayers and to form zones of lysis or plaques.

Monolayers of target cells were prepared on poly-L-lysine-coated Falcon plastic Petri dishes as described before[4]. The effector lymphocytes were generated after either *in vivo* sensitisation or *in vitro* sensitisation against tumour allografts. Known numbers of effector lymphocytes were added on the target monolayers and the plates were incubated at 37 °C in an atmosphere of 5% CO_2. After incubation plates were washed with minimum Eagle's medium (MEM), dead tumour cells were stained with eosin, and the plates were washed again with MEM. Zones of dead target cells or plaques were counted under the microscope. A cluster of more than four dead target cells was considered a plaque (Fig. 1).

Several representative experiments are shown in Table 1. Both the *in vivo* and *in vitro* sensitised alloimmune lymphocytes (BALB/c anti-EL-4) form plaques on EL-4 target-cell
Fig. 1 A monolayer prepared with EL-4 tumour cells and plaques developed by *in vitro*-generated anti-EL-4 cytotoxic lymphocytes. *a*, Arrows point to plaques ($\times 125$); *b*, a plaque ($\times 250$); *c*, a monolayer background lacking plaques ($\times 250$).

monolayers. The specificity of plaque formation was indicated by the absence of plaques when unrelated target-cell monolayers (G-35) were used. Furthermore, normal lymphocytes or lymphocytes cultured alone did not form plaques. A linear relationship was usually obtained between the number of effector cells plated and the number of plaques observed, indicating that each plaque was presumably formed by one CTL. As expected, the *in vitro*-generated secondary response yielded many more plaques when compared with the *in vivo* immune response (experiments 1 and 4, Table 1). Treatment of effector lymphocytes with specific anti-thymocyte serum and complement abrogated completely

both the formation of plaques and the cell-mediated cyto-toxic activity obtained by the ^{51}Cr-release assay (experiment 5, Table 1). Neither serum nor complement alone had an adverse effect on plaque formation. These results demonstrated that alloimmune lymphocytes form specific plaques on corresponding target cell monolayers and that the effector cells are thymus-derived lymphocytes.

The relationship between plaque formation and the release of ^{51}Cr from target cells as measures of cell-mediated cytotoxicity was investigated. In all cases, when effector populations produced plaques, they also showed cytotoxicity by ^{51}Cr release (Table 2). In several experiments, effector cells with strong cytotoxic activity yielded a large number of cytolytic plaques. That the same population of effector cells exerted these two properties, is corroborated by the findings that reduction of cytotoxic activity by absorption on specific target cell monolayers was paralleled by a marked reduction in the number of plaques (experiment 1, Table 2). Experiments with *in vitro* sensitisation of C57BL/6 splenocytes against syngeneic EL-4 leukaemia cells have

Table 1 Frequency of CTL in alloimmune lymphocyte preparations

Experiment no.	Effector cells Sensitisation	Specificity	No. of cells plated	Monolayer	Plaque-forming units Observed	Per 10⁶	%

Effector cells (alloimmune lymphocytes) were prepared after *in vivo* and *in vitro* immunisation. Cytotoxic cells were generated *in vivo* by intraperitoneal inoculation of 2×10^7 EL-4 (H-2^b) into BALB/c (H-2^d) mice for anti-EL-4 activity, or 2×10^7 G-35 (H-2^d) syngeneic in BALB/c into C57BL/6 (H-2^b) for anti-G-35 activity. The mice were killed 9–10 d later and the peritoneal fluid exudate was aspirated by a Pasteur pipette after several washes of the cavity. The cells were washed, suspended in MEM at 10^7 per ml and samples of 1 ml were plated on plastic tissue culture dishes. The plates were incubated at 37 °C for 1 h and the non-adherent cells were recovered, counted for viability by Trypan blue dye exclusion and suspended in RPMI or MEM at desired concentrations. Lymphocytes were generated *in vitro* as follows. Mice were primed with 2×10^7 tumour cells and 40–60 d later they were killed and their spleens were removed in sterile conditions. The cells were teased apart in balanced salt solution (BSS), filtered through a nylon screen and washed once. Cells were then treated with Gey's solution to lyse red blood cells, washed twice with BSS and resuspended to 10^7 per ml viable cells in RPMI 1640 containing 10% foetal calf serum (FCS). The stimulating tumour cells were prepared as above for responding cells and treated with 30 μg mitomycin C per 10^7 cells. The cells were incubated at 37 °C for 40 min and washed four times with BSS and resuspended to 5×10^6 per ml viable cell in RPMI 1640 containing 10% FCS. Sensitisation was done in 50-ml Falcon conical tubes in which 3 ml of the responder cells (30×10^6 per ml) and 1 ml of stimulator (5×10^6 cells) were mixed and the total volume was brought up to 10 ml. The tubes were incubated for 3–5 d at 37 °C in a 5% CO_2 incubator. At the end of incubation, dead cells were removed using Ficoll–Isopaque. The cell preparation was then brought to the desired concentration in RPMI 1640 + 10% FCS and used for plaque assays or for ^{51}Cr-release cell-mediated cytotoxicity. Monolayers were prepared on 35×10-mm Falcon plastic dishes (no. 3001) coated with poly-L-lysine. One ml of poly-L-lysine (50 μg ml^{-1}, molecular weight 85,000, Sigma, Mi) in phosphate-buffered saline (PBS) (Dulbecco's PBS + $CaCl_2$ + $MgCl_2$) was added to each plate and left at room temperature overnight. Plates were washed with PBS before use. Target cells used to prepare the monolayers were either tumour cells or peritoneal macrophages (PM). Tumour cells (EL-4 and G-35) were maintained in ascites form *in vivo*. The ascites fluid containing tumour cells was washed and tumour cells were suspended in PBS at 10^7 per ml. Target cells (1 ml) were added to each plate, which were then left at room temperature for 10 min, centrifuged at 200g for 5 min at 20 °C and washed three or four times with PBS. In most experiments, 1 ml of 0.2% Trypan blue in saline was added to each plate, left at room temperature for 3–5 min, washed with PBS, and monolayers were examined for viability under the microscope. PMs were derived from mice inoculated with 3 ml of thioglycollate 3 d before collection. Peritoneal cells were prepared as described above for tumour cells. Plaque-forming units were estimated as follows. Effector lymphocytes were added at desired concentrations in a total of 1 ml per plate. Plates were incubated at 37 °C in an atmosphere 5% CO_2 for 2–4 h. Plates were washed with 2 ml MEM, and stained with 1 ml of 1% eosin dye for 3–5 min. The plates were washed with PBS and examined under the microscope. In several experiments, monolayers were fixed by treating the plate with 0.2% formaldehyde overnight at 5 °C and then washed with PBS. Plaques were scored under the microscope. Manual interplay with the condenser facilitated location of plaques. In general, the plates were placed on a microscope slide with a square drawn calibrated for 1/5 the surface area of the Petri dish. The total number of plaques per square was routinely counted and the number of plaques per 10^6 lymphocytes was thus estimated.

*In this experiment each effector cell concentration was tested in triplicate.

†Treatment with specific anti-thymocyte serum and C' (ref. 11) was as follows: 0.3 ml of 1:10 dilution of specific rabbit anti-thymocyte serum and 0.3 ml of 1:10 normal rabbit serum (absorbed with tumour cells) as source of complement was added to 10^6 lymphocytes; the mixture was incubated at 37 °C for 45 min and the cells were washed with MEM and resuspended at the original concentration.

Table 2 Correlation between plaque formation and cell-mediated cytotoxicity

Experiment no.	Effector cells	No. of cells plated	Monolayer	Plaque-forming units Observed	%	% CMC to ^{51}Cr EL-4
1	BALB/c anti-EL-4	1×10^5	EL-4	1,650	1.65	97.0
	BALB/c anti-EL-4 absorbed on EL-4 monolayer*	1×10^5	EL-4	225	0.22 (87)†	49.1 (49)
	BALB/c anti-EL-4 absorbed on G-35 monolayer	1×10^5	EL-4	1,540	1.54	83.6
	BALB/c anti-EL-4	1×10^5	G-35	0	0	0
2	BALB/c anti-EL-4	1×10^5	EL-4	420	0.42	58.7
	Normal BALB/c spleen	5×10^5	EL-4	15	0.003	0

Effector cells were generated *in vitro* in one way mixed lymphocyte–tumour cultures. 5×10^6 BALB/c splenocytes were mixed with 2.5×10^6 mitomycin C ($50 \ \mu g \ ml^{-1}$)-treated EL-4 cells in tubes (125×16 mm; Falcon no. 3033) in RPMI culture medium supplemented with 10% foetal calf serum. Six days later cultures were collected and the cells were separated on Ficoll–Hypaque to remove dead cells. Cell-mediated cytotoxicity (CMC) with ^{51}Cr target cells was assayed as described previously[4] at an effector–target cell ratio of 10:1.
*Absorption on monolayers was done as described before[4].
†Numbers in parentheses represent percentage reduction.

produced 5–10 times less plaque-forming units (0.04–0.12%) than allogeneic sensitisation. The ^{51}Cr release in the syngeneic sensitisation was weaker than the allogeneic system.

Several parameters have been examined in an effort to generalise the applicability of the CTL plaque assay and also to optimise the sensitivity of the assay. For example, we found that monolayers can be prepared with target cells other than tumour cells, such as thymocytes or thioglycollate-induced peritoneal macrophages (experiment 6, Table 1). The plates containing the plaques can be fixed with 0.2% formaldehyde and kept at 4 °C without any significant change in the number of plaques. Spontaneous lysis of target cells on the monolayer interferes with plaque reading. Plaques were assayed only when the monolayer target cell showed >95% viability. To distinguish between dead cells present at the initiation of incubation from those which occurred after incubation, a double staining technique was used. The target cell monolayers were first stained with Trypan blue and after plating of the lymphocytes, the monolayers were stained with eosin. The time of incubation of the assay varied from 2 to 5 h depending on the source of effector cells used. *In vitro* sensitised cells required less than 2 h, whereas the *in vivo* sensitised lymphocytes required 4 h (experiment 4, Table 1). Longer incubation periods resulted in a mixture of clear and stained plaques, and these were difficult to quantify and reproduce.

The percentage of CTL in mixed alloimmune preparations as obtained by the plaque assay ranged from 0.05 to 2% of the total plated on the monolayer. These percentages may be underestimates due to the limitations of the assay conditions. For example, (1) CTL may be heterogeneous in their state of differentiation and may express different degrees of cytotoxic activity. In such cases, only CTL that can kill more than four target cells will be scored while CTL which will kill less than four target cells will be missed in our assay. (2) The plating efficiency is not high, that is, CTL with high affinity to target cells may be preferentially selected, and (3) lysis of target cells may not be revealed by dye-exclusion techniques.

Although our plaque assay measured directly the number of CTL, indirect methods have been reported which estimate the number of CTL by their ability to bind to target cells and form conjugates. For example, with alloimmune peritoneal exudate cells (PEC), the number of CTL were estimated to be >6% by Martz[5] and up to 35% by Berke *et al.*[6].

It is difficult to ascertain from our studies the precise number of precursors of CTL present in a non-immune lymphoid cell population. Such numbers, however, have been reported for precursors which mediate mixed lymphocyte culture and graft *versus* host reactions. It was reported that 1–3% responsive cells became stimulated to proliferate in the mixed lymphocyte interaction[7], 1–2% induced local graft *versus* host reaction[8], 6% of parental T cells bear surface

receptors which share idiotypic determinants with IgG fractions of alloantibody specific for a particular major histocompatibility complex (MHC) haplotype[9], and 4.5–6% participate in a systemic graft *versus* host reaction in the rat[10]. If CTLs arise by expansion of the precursor pool after antigenic stimulation then the percentage of uncommitted precursor CTL for one MHC will be less than 1%. This percentage agrees with that postulated by Ford *et al.*[10].

In conclusion, the plaque assay described here was shown to enumerate specific cytotoxic T lymphocytes present in a mixed cell population. This modified plaque assay should be helpful in elucidating several aspects of cell-mediated immunity such as cytotoxic potential, affinity, heterogeneity, specificity, and morphological characteristics of effector T lymphocytes once isolated.

In vitro and *in vivo* radiosensitivity of human tumour cells obtained from a pancreatic carcinoma xenograft

HUMAN tumours show a wide range of clinical response to radiotherapy, but the extent to which this reflects differences in intrinsic cellular radiosensitivity, extent of tumour cell hypoxia, or host reaction against the tumour is unknown. For tumours in laboratory animals, various assays for clonogenic cells are available. These have shown that the range

of radiosensitivity of aerobic cells is quite narrow[1,2] and that the hypoxic fraction of clonogenic cells within tumours of palpable dimensions is often in the range 10–35%. Until now the lack of satisfactory assay for clonogenic cells has prevented similar studies on human solid tumours treated *in vivo*. We have developed two assays for clonogenic cells from a human metastatic pancreatic carcinoma propagated as a xenograft in immune-suppressed CBA/lac mice. This xenograft was one of a series established by Pickard *et al.*[3].

In the first assay, tumour-cell suspensions were incubated in Ham's medium with the addition of 15% calf serum, 0.3% agar and rat red blood cells in 17-mm diameter test tubes using a double layer technique. Colonies of 50 cells or more were counted at 28 d and the plating efficiency was 20–40%. In the second assay, tumour-cell suspensions in medium, serum and agar were grown in diffusion chambers implanted into the peritoneal cavity of C57BL mice, previously treated with whole-body radiation. Colonies, growing slightly more quickly than in the first assay, were counted at about 18 d and the plating efficiency was 10–20%. Detailed descriptions of the experimental methods are being prepared for publication. Chromosomal analysis of the cells after 16 d growth in culture verified a human karyotype, with aneuploidy ranging from 42 to 68 chromosomes and a mode of 62.

Tumours measuring 5–8 mm in diameter were grown in the leg muscles of immune-suppressed mice and were irradiated *in vivo* using ^{60}Co γ rays. The animals were killed and the tumours removed either immediately after irradiation or 18 h later, and cell suspensions were prepared for assay. Acute hypoxia was induced by killing mice by nitrogen asphyxiation 15 min before the start of irradiation. *In vitro* aerobic irradiation was carried out on freshly prepared tumour-cell suspensions.

The results of *in vitro* irradiation and *in vivo* irradiation

Fig. 1 Survival curves for the xenografted tumour cells treated with single doses of γ radiation. ×, Cells irradiated as a single-cell suspension in aerobic conditions *in vitro* and assayed using the *in vitro* colony assay. The other data are for tumours irradiated *in situ*: ○ ●, assay immediately after irradiation in air-breathing mice; △ ▲, assay 18 h after irradiation in air-breathing mice; □ ■, assay immediately after irradiation in nitrogen-asphyxiated mice. Open symbols indicate the results of the diffusion chamber assay; closed symbols the results of the *in vitro* assay.
in air-breathing and hypoxic conditions are shown in Fig. 1. The two assays agree well and we are unable to detect any systematic differences between them. The *in vitro* cell survival curve has a D_0 of 96±9 rad. (D_0 is the dose that reduces survival by 63% on the exponential part of the curve.) The *in vivo* air-breathing survival curve for animals killed immediately after irradiation shows an initial sensitive component and a radioresistant component, the D_0 of which is 305±16 rad. The D_0 values for the terminal parts of the other two curves are not significantly different from this and we have therefore drawn the three curves parallel. From the vertical displacement of the hypoxic curve from the lowest air-breathing curve we calculate an hypoxic fraction of 0.25. The oxygen enhancement ratio is 3.1±0.4. The data obtained on tumours that were taken 18 h after irradiation, are displaced vertically from the other air-breathing curve by a factor of 2.2. This displacement shows that the fractional survival of tumour cells obtained at 18 h after irradiation was greater than when the cells were removed immediately. Two mechanisms may be involved: the repair of potentially lethal damage or the selective death or disappearance during the 18-h period of lethally damaged cells. Repair of potentially lethal damage has been reported in cell populations irradiated *in vitro* and *in vivo*[4,5]. The present data suggest that the 18-h curve is parallel to the other two curves down to radiation doses as low as 200 rad, but more data are required to confirm this.

Limited clinical experience with irradiation in pancreatic carcinoma suggests that this is not usually a radioresponsive tumour[6]. It is therefore of interest that the D_0 values which we have obtained are within the range of values determined using tumours of laboratory animals. The hypoxic fraction is also no less than has been found in experimental tumours, but the significance of this must be interpreted with caution because of the possible influence on this parameter of vascular stroma derived from the mouse. One interpretation of these data, however, is that the response of pancreatic carcinoma to radiotherapy is limited by the high proportion of hypoxic cells. This provides support for current efforts to improve clinical therapeutic response by the use of chemical radiosensitisers or high LET radiation.

In vivo hyperthermia of Yoshida tumour induces entry of non-proliferating cells into cycle

HYPERTHERMIA (temperatures in excess of 40 °C) is at present receiving widespread interest as a potential method of treating cancer. High temperature can selectively destroy several types of cancer cell *in vitro* and *in vivo*[1-3], and extensive lysis has been achieved clinically in limb tumours maintained at 41.5–43.5 °C for 6–8 h (ref. 1). In spite of these encouraging findings, fundamental information is
Fig. 1 Growth curve of the Yoshida sarcoma (■), and tumour volume changes after curative hyperthermia (intratumour temperature 42 °C for 1 h) on day 9 after implantation (●). Figures in brackets indicate the numbers of tumours (rats) used to construct the curves.

needed on the factors governing tumour response to heat before the place of this approach in cancer therapy can be defined. Inadequate heating of the Yoshida rat sarcoma (in terms of temperature and/or time relative to tumour volume) increased tumour metastasis and suggested an influence of population kinetics on the outcome of heating[4,5]. Work *in vitro* has shown hyperthermic cell killing to be preferentially cycle[6,7] and phase[8-11] oriented. Implication of cell kinetics in the response to heat is further suggested by work on the rabbit VX2 carcinoma. A single heat application (intratumour temperature 42 °C for 1 h) does not destroy this tumour, whereas three such treatments if applied within the tumour cell generation time are curative[12]. This report describes changes in the *in vivo* cell kinetics of the Yoshida sarcoma after curative heating at 42 °C, with emphasis on stimulation of non-proliferating tumour cells into cycle.

Details of the history and maintenance of the solid Yoshida sarcoma are described elsewhere[2]. For this work, the tumour was grown in the dorsum of one hind foot of the rats. After implantation of 0.1 ml homogenate the tumour grew progressively killing the host by metastasis in approximately 45 d. The tumour volume growth curve exhibited three distinct phases (Fig. 1)—an initial lag phase, followed by an exponential phase from day 5 to 10, and finally a slower growing 'tail' phase in keeping with the Gompertz growth function for solid tumours[13].

Tritiated thymidine (^{3}H-TdR; Radiochemical Centre, Amersham; 1 mCi ml[-1]; specific activity 21 Ci mmol[-1]) was diluted for injection with normal saline. ^{3}H-TdR was given intraperitoneally to the rats in the following doses: animals to be killed for the percentage labelled mitoses (PLM) and 1-h (flash) labelling work were given a single 400-μCi injection in 1 ml saline; animals for repeated tumour labelling experiments received 100 μCi ^{3}H-TdR every 6 h, and a further 100 μCi 1 h before killing. Autoradiographs of 4-μm paraffin-embedded hemisections of the tumours were prepared using the 'dipping' technique[14] with Ilford K-2 emulsion. After 14 d exposure time, the autoradiographs were processed with D-19 developer and F-5 fixer, and stained with haematoxylin and eosin. For the PLM curves, 500 anaphases and metaphases were counted 'blind', and for the flash and repeated labelling indices (% labelled cells) a

total of 2,000 cells were scored. Vincristine (Oncovin, Eli Lilly, Basingstoke, UK) was injected at a dose of 1 mg kg[-1] in 1 ml saline. Paraffin sections (4 μm) were stained as above and the mitotic index (% mitoses) determined by counting 4,000 cells.

The PLM curve of the 1.0–1.5 ml Yoshida sarcoma was constructed from results obtained with 60 tumours examined at 1-h intervals for 30 h. The median cell cycle times shown in Table 1 were obtained by graphical inspection of the curve at the 50% points. The flash-labelling index (I_L), or percentage labelled cells 1 h after exposure to ^{3}H-TdR, was 52.5%. These data were used to determine the growth fraction (fraction of the tumour cell population that is actively proliferating, I_P; ref. 15), assuming exponential growth and age distribution of the cells. The birth rate (K_B), or rate of production of new cells, was estimated by mitotic blocking with vincristine (Fig. 2), birth rate being the slope of the line[16]. Tumour doubling time (derived from the slope of the growth curve, Fig. 1) and birth rate data were used to estimate the cell loss factor[17] (or ratio of the rate of cell loss to birth rate).

Tumours of 1.0–1.5 ml were heated at 42 °C (intratumour temperature) for 1 h by immersing the foot bearing the tumour in a water bath. In these conditions, all tumours regressed completely within 14 d (Fig. 1) with cure of the host rats. The effect of hyperthermia on I_L is shown in Fig. 3, which provides an indication of the fraction of cells synthesising DNA over the 9 d after heat treatment. For the first 24 h after heat treatment, I_L was depressed but recovered to near control levels at 2 d; it then fell progressively to zero by 9 d as the tumour regressed. Changes occurring in the first 48 h after heat treatment were examined in more detail by repeated ^{3}H-TdR-labelling (Fig. 4). In controls repeatedly labelled every 6 h, the labelling index increased to a plateau level of almost 80% labelled cells after 8 h. With curative hyperthermia, a complex sequence of events ensued. Labelling was grossly depressed immediately after heating, but increased rapidly to a maximum of 60% after 8 h; an equally rapid decline in labelling index to a minimum of 5% at 14 h then preceded a final perturbed recovery to a plateau of approximately 60% labelled cells 36 h after heat.

The decline in labelling to 5% at 14 h after heat can only be due to cell death. Thus, more than 90% of the cells proliferating (P cells[15]) after hyperthermia had been lost by 14 h, the median cell cycle time of the tumour. This would imply that cells damaged at the time of heating had progressed through one cell cycle and died, possibly in mitosis. It seems unlikely that the rapid recovery of labelling and

Fig. 2 Mitotic accumulation after vincristine arrest in untreated Yoshida sarcoma. Cell birth rate (from slope) = 0.094/2 = 0.047 cells h[-1].
Fig. 3 ³H-TdR flash-labelling index in the Yoshida sarcoma after curative hyperthermia. From 30 min onwards, each point is the mean of two separate experiments.

Table 1 Cell kinetic parameters of the Yoshida sarcoma

Tumour volume (ml)				1.0–1.5
Doubling time (h)				36

T_C	T_S	$T_{G_1}*$	T_{G_2}	T_M
(14.1)	(9.7)	(—)	(4)	(0.4)

Flash (1 h) labelling index	(I_L)	0.525
Growth fraction	(I_P)	0.678
Birth rate (cells h⁻¹)	(K_B)	0.047
Cell loss factor	(φ)	0.590

*Tumour has no detectable G_1 phase.

mitosis (as determined by vincristine blockade) from 14 to 36 h is caused by cells in cycle at the time of heat treatment. A more likely explanation is the entry into S phase of a population of cells not proliferating (Q cells) at the time of heat treatment; this would repopulate the tumour from 14 h onwards. Further evidence in favour of this is shown in Fig. 4. Repeated labelling was terminated at 14 h after heat, the time of maximum cell death; only a small increase in labelling was subsequently observed. When repeated labelling was commenced at 14 h, the labelling index recovered to the 60% region by 30 h after heat. These two experiments support the hypothesis that the recovery in proliferation from 14 h after heat in this tumour is mainly due to cells in the non-proliferating compartment at the time of heat treatment.

The PLM curve of the tumour 30 h after heat treatment provided durations for the cell cycle components that were not significantly different from those of the untreated tumour (Table 1). This is further substantiation that the changes in cell kinetics produced by curative hyperthermia are primarily in population size and the relationship of the P and Q cell compartments, rather than in cell generation times.

The data imply a preferential destruction of P cells in the Yoshida sarcoma by hyperthermia followed by the

recruitment of Q cells into cycle. Similar effects have been observed after radiation[18] or chemotherapy[19], and the timing of recovery has been used to plan fractionated therapy regimens. In spite of apparent kinetic recovery after heat treatment, the tumour regressed within 14 d with complete cure of the animals. The sensitivity of the Yoshida sarcoma to hyperthermia at volumes of 1.0 to 1.5 ml may be due to its high growth fraction ($I_P=0.678$) and the dominant position of the relatively sensitive S phase[10,11] in its cell cycle (9.7 out of 14.1 h). The failure of cells surviving the first 48 h after treatment to maintain the growth of the tumour implies an inability to repair sublethal damage and/or the operation of host factors in the destruction of the heat-treated tumour. ³H-TdR-labelled cells and mitoses were observed in tumour sections up to 6 d after heat treatment. This confirms *in vitro* findings[20] that several mitoses (up to 10 in the case of the Yoshida tumour) may occur before the expression of lethal hyperthermic damage.

Antibodies to melanoma cell and BCG antigens in sera from tumour-free individuals and from melanoma patients

THE *Mycobacterium bovis* strain BCG shares antigenic components with several neoplasms, including human malignant melanoma[1–5]. Other species of bacteria also have antigenic similarities with a guinea pig hepatoma[6]. Antibodies to mycobacteria and other bacterial antigens are universally present in sera from normal humans[7,8]. Since there is a broad range of shared or cross-reactive antigens among mycobacteria and unrelated microorganisms[9], it is

conceivable that an immune response by normal humans to mycobacteria has been induced by exposure to taxonomically unrelated microorganisms ubiquitous in the environment. Cytotoxic reactions by lymphoid cells from normal animals and humans to many kinds of tumour cells have been reported[10-15]. Antibodies in sera from patients with various neoplasms have often been observed that react with antigens derived from their own tumours or from those of the same histological type[16-18]. Humoral responses to tumour-associated antigens have also been noted in sera from normal humans, gibbons and mice[19-21]. We have investigated whether sera from normal, tumour-free humans contain antibodies which can react with melanoma-associated as well as with BCG antigens. If this were the case, perhaps immunological reactions by normal humans to certain tumours are widespread and reflect previous sensitisation by microorganisms.

BCG (Glaxo) was obtained from the US–Japan Cooperative Medical Science Program. Subcultures of BCG were grown, killed by heat, washed and disrupted by sonication. After centrifugation the resulting supernatant was separated and is referred to as BCG-SS (ref. 3).

Melanoma cells were grown in tissue culture and were provided by Dr G. Moore, Denver General Hospital[4]. They originated from a biopsy of a metastatic inguinal node of a male, aged 43 yr, whose primary lesion was on the heel of his right foot. They were treated with 3 M KCl as described before[3,4]. These KCl extracts have been used previously to investigate antigenic relationships between human malignant melanoma cells and BCG. It has been suggested that the antigenic determinants from this melanoma cell line which are shared with BCG are the group-specific cytoplasmic tumour antigens in melanoma cells[5].

The melanoma cell KCl extract and BCG-SS were labelled with ^{125}I using a modified chloramine T method as previously described[3,4] and are referred to as ^{125}I-mel and ^{125}I-BCG, respectively. The labelled antigens were diluted in 1 : 100 normal human serum in borate buffer so that their concentrations ranged from 0.01 to 0.008 μg N per 0.1 ml and so that the c.p.m. of 0.1 ml of labelled antigens used in the test procedures were 10,000–15,000.

The primary interactions between labelled test antigens and antibodies were analysed by precipitation of ^{125}I-labelled antigen–antibody complexes with anti-human IgG (anti-HGG). The amount of anti-HGG required to precipitate all

the HGG in a given test sample was determined as previously described[22]. Inhibition and absorption experiments were also carried out to evaluate the specificity of the observed reactions. Details of these procedures have been described before[3,4].

Sera from 63 patients with malignant melanoma were obtained shortly after surgery and before the patients were started on a chemoimmunotherapy programme. Thirteen patients had stage 1 disease, four had stage 2, 29 had stage 3 and 17 were stage 4. Ages ranged from 21 to 72 yr. There were 41 male and 22 female patients. Control sera were from 50 healthy subjects, most of whom were personnel at the National Jewish Hospital and Research Center (NJHRC). Sera were not obtained from subjects who had been in contact with human tumours in the laboratory. Ages ranged from 25 to 50 yr and there were 20 males and 30 females. Sera were obtained from two patients at the NJHRC who were under treatment for advanced, active tuberculosis.

When sera from all the patients and normal subjects were tested for their capacity to bind ^{125}I-BCG and ^{125}I-mel there was a wide range in their capacity to bind both radiolabelled antigens (Fig. 1a and b). As a group, sera from patients with melanoma bound ^{125}I-BCG to about the same extent as did sera from normal subjects. The capacity of sera from 17 patients with stage 4 disease to bind ^{125}I-BCG was somewhat less than that of normal sera. These differences, however, were not significant $(P<0.2)$. When the same sera were reacted with ^{125}I-mel, more antigen was bound by normal sera than by sera from the melanoma patients $(P<0.025)$. The overlapping of data between these two groups made it impossible to correlate disease and the amount of antigen bound by individual serum samples. When sera from patients with stage 4 were compared with normals they were found to have significantly lower $(P<0.005)$ binding values. Lower antibody levels to antigens have been shown when circulating antigen, soluble antigen–antibody complexes or anti-idiotype antibodies are present, and this may be the case in some patients with far advanced melanoma[18,23-26].

A series of experiments was then undertaken to evaluate the specificity of the binding data. The capacity of unlabelled BCG-SS to inhibit binding of ^{125}I-BCG and ^{125}I-mel by selected sera was examined. Sera from 11 melanoma patients and from seven normal subjects were preincubated

Fig. 1 Results of binding tests using ^{125}I-BCG (*a*) and ^{125}I-mel (*b*) expressed as percentage labelled antigens bound by 0.1 ml of a 1:5 dilution of whole serum. 1, All melanoma (63); 2, Stage 4 melanoma (17); 3, no disease (50).
Fig. 2 Inhibition of binding of ^{125}I-BCG (*a*) and ^{125}I-mel (*b*) by sera from normal (open symbols) and melanoma (closed symbols) patients after preincubation of sera with dilutions of BCG-SS.

with 300 μg N unlabelled BCG-SS. Control samples were incubated with borate buffer. Twenty-four hours later, ^{125}I-BCG and ^{125}I-mel were added and binding capacities of the antisera were determined. The percentage decrease of binding is shown in Table 1. Unlabelled BCG-SS considerably inhibited the binding as expected to ^{125}I-BCG. To a lesser extent it also reduced the binding by most of these antisera to ^{125}I-mel. This is compatible with observations that some antigenic components are shared between BCG and melanoma cells[4].

Inhibition studies were carried out in greater detail using sera from three melanoma patients and two normal individuals. Serial dilutions of 0.1 ml of unlabelled BCG-SS were tested for their capacity to inhibit binding of 0.1 ml of ^{125}I-BCG and ^{125}I-mel to 1 : 5 dilutions of antisera. Controls consisted of 0.1 ml of borate buffer added to the diluted antisera. After overnight incubation, labelled BCG and melanoma antigens were added and binding to these antigens was determined. As little as 2.8 μg N unlabelled BCG-SS inhibited the binding by both normal and melanoma antisera to ^{125}I-BCG, and with increasing amounts there was slightly more inhibition (see Fig. 2*a* and *b*). When ^{125}I-mel

was the antigen there was similar inhibition of binding by four of the five sera tested, but more BCG-SS was required. As Fig. 2*b* shows, 72 μg N caused slight inhibition and 300 μg N were considerably more effective.

Sera from two melanoma patients, two normal subjects and two patients with active tuberculosis were then absorbed with 3×10^7 intact melanoma cells, or with 2×10^8 normal human spleen cells, and then reacted with ^{125}I-mel (Table 2). Sera from patients with tuberculosis were included because they generally have greater capacities to bind ^{125}I-BCG than do sera from normal subjects[7]. After absorption with melanoma cells there was a marked reduction in binding to ^{125}I-mel by all the sera. Absorption of the same sera with normal human spleen cells showed only slight decreases, except for normal serum No. 1, where there was a more moderate decrease in binding. Not shown in Table 1, there was no reduction in binding to ^{125}I-BCG after absorption with 3×10^7 melanoma cells. Unfortunately, greater numbers of melanoma cells were not available for additional absorptions.

Our previous studies and those of others have indicated that antibodies to mycobacteria and various unrelated bacteria and fungi are present in sera from humans with no history of exposure to these microorganisms[7,8]. In this study antibodies to a melanoma-associated antigen were detected in sera from the normal subjects tested. The binding and inhibition test results indicated that the reactions by normal sera were true immunological manifestations even though the specific stimulating antigen(s) was not identified. Because

of the antigenic relationships between BCG and melanoma cells[2,4,5], antibodies to melanoma-associated antigens might have been induced by exposure to mycobacteria or other microorganisms. Because the sharing of antigens between tumour cells and bacteria may be widespread[6], immune responses, whether cellular or humoral, may exist in normal humans to various tumours. Some of the frequently reported and unexplained cellular and humoral reactions to tumour antigens by normal persons[13–15] may have been induced by exposure to microorganisms. Immune responses by normal subjects[19–21] or animals to tumour antigens are often referred to as "natural" or "nonspecific". Results of this and previous studies[2,4,5] imply rather that immune reactions by normal subjects to melanoma-associated antigens can be the result of direct and specific stimulation by antigens of mycobacteria.

It is possible then that just as normal humans respond immunologically to bacterial antigens, they may also respond immunologically to some tumour antigens. If this is the case then immune responses by patients to tumour antigens may sometimes represent an elevation of an "isoimmune" state, rather than a new actively acquired immune response and may influence the course of neoplastic disease.

Inhibition of tumour growth *in vivo* and *in vitro* by prostaglandin E

PROSTAGLANDIN E (PGE), both endogenous and exogenous, has been shown to inhibit significantly the rates of tumour-cell proliferation *in vitro*[1–4]. Suppression of PG biosynthesis with indomethacin[5,6] resulted in stimulation of cell replication, an effect which was readily reversed by the addition to the medium of small amounts of exogenous PGE_1 (10 ng ml^{-1}) (ref. 5). Corticosteroids have recently been shown to inhibit the biosynthesis of PGE by rheumatoid synovia[7] and mouse fibrosarcoma $HSDM_1$ (ref. 8) *in vitro*; the mechanism of this action seems to be by interfering with the release of arachidonic acid from phospholipids[9]. To evaluate further the possible role of PGE in the control of tumour-cell proliferation, we have studied the effects of hydrocortisone and indomethacin on the growth rate of B-16 mouse melanoma *in vitro*. The studies demonstrate that both compounds cause significant stimulation of tumour-cell replication *in vitro*, associated with inhibition of PG biosynthesis, albeit by two different mechanisms. In addition, we have extended the observations on the effects of exogenous PGE_1, by demonstrating that subcutaneous administration of 16,16-dimethyl-PGE_2-methyl ester significantly inhibits tumour growth *in vivo*.

The *in vitro* studies were all performed using B-16 melanoma cultured in modified McCoy's 5A medium, containing 15% foetal calf serum, glutamine (220 µg ml^{-1}), penicillin (100 U ml^{-1}) and streptomycin (0.1 mg ml^{-1}). Cultures were maintained in 75-cm^2 plastic T-flasks at 37 ± 0.5 °C in humidified 95% air, 5% CO_2, and media were changed on alternate days. Media containing PGE_1, indomethacin and hydrocortisone were sterilised by Millipore filtration. Control media contained identical concentrations of ethanol (< 0.01%). For counting, cells were removed using 0.1% trypsin, EDTA, 1.5 mg ml^{-1}, and mechanical scraping and were resuspended in medium. At least triplicate cell counts were performed using a haemocytometer; cell viability, as determined by vital dye exclusion[10] (Nigrosin 0.2%), ranged from 92.5 to 100% and was not influenced by the addition of exogenous PGE_1, indomethacin, or hydrocortisone. PG concentrations in media and supernatants were measured by radioimmunoassay after organic solvent extraction and silicic acid chromatography as described previously[5,11].

In an initial experiment, 2×10^5 B-16 cells were plated in duplicate flasks containing PGE_1 (1 µg ml^{-1}), indomethacin (10^{-8} M), or hydrocortisone (10^{-6} M). Exogenous PGE_1 caused a mean 24.4 ± 6.1% inhibition of cell replication (Fig. 1); inhibition was statistically significant at days 4 and 6 ($P < 0.05$ and $P < 0.001$, respectively). As in previous experiments, indomethacin caused a significant (35.5%) inhibition of PG concentrations in the media and resulted in a mean 17.0 ± 3.2% stimulation of cell replication, which was statistically significant at days 4 ($+18\%$; $P < 0.05\%$) and 6 (22%; $P < 0.005\%$). Hydrocortisone produced similar results, significantly stimulating cell proliferation and decreasing endogenous PGE concentrations in the media.

The relationship between the concentration of exogenous PGE and the degree of inhibition of cell proliferation was tested in duplicate experiments in which 0.5, 1.0, 2.0, 5.0 and 10.0×10^5 B-16 cells were exposed to PGE_1 (1 µg ml^{-1}) for 48 h. There was a gradual dose–response curve with higher ratios of PGE/cell causing more inhibition (31.4%, 37.5%, 25.8%, 22.8% and 22.4%, respectively).

The effect of hydrocortisone on the proliferation rate was investigated further by plating 2.5×10^5 cells from one stock culture in duplicate control media as well as duplicate media containing hydrocortisone at 0.3×10^{-5} M, 10^{-6} M, and 10^{-7} M. All three concentrations of hydrocortisone caused significant stimulation of cell replication (Table 1). Maximal stimulation (mean 36.5%) was achieved with 10^{-6} M hydrocortisone; comparable data for 0.3×10^{-5} M and 10^{-7} M were 18.1% and 32.2%, respectively. In spite of the large cell numbers achieved, there seemed to be no contact inhibition of growth. Total PGE biosynthesis (cells + media) was linear in control conditions and was inhibited significantly by hydrocortisone at all three concentrations (Fig. 2). Each of the three concentrations of hydrocortisone inhibited PGE synthesis approximately 50%. The effect of hydrocortisone on PGE concentrations was similar in media and cells, which rules out the possibility that hydro-

Table 1 The effect of hydrocortisone on B-16 proliferation *in vitro*

Hydrocortisone	Number of cells × 10⁶			
	0 h	48 h	96 h	144 h
0	0.25	0.40 ± 0.01	4.85 ± 0.55	9.95 ± 0.55

10⁻⁶ M + PGE₁, 10 ng ml⁻¹	0.25	0.47 ± 0.04	4.65 ± 0.05	9.55 ± 0.65

The effect of hydrocortisone on B-16 proliferation *in vitro*. Data represent mean ± s.d. of duplicate determinations at each time point; at least triplicate counts were performed for each determination. Viability exceeded 95% in all cultures. Compared with control values, hydrocortisone caused mean stimulation of cell replication: 0.3×10^{-5} M, 18.1%; 10^{-6} M, 36.5%; 10^{-7} M, 32.5%; 10^{-6} M + 10 ng ml⁻¹ PGE₁, 3.2%.

cortisone only inhibited the release of PGE from cells. Using regression analysis, the degree of stimulation was not significantly related to the degree of inhibition of prostaglandin biosynthesis ($P > 0.05$). Therefore, in order to verify that the effect of hydrocortisone on stimulation of cell replication was, in fact, a result of its induced inhibition of prostaglandin biosynthesis, an identical experiment was carried out in which cells were grown in media containing both 10^{-6} M hydrocortisone and exogenous PGE₁, 10 ng ml⁻¹ (the approximate endogenous concentration in control conditions). Small concentrations of exogenous PGE₁ normalised the growth rate (Table 1).

Fig. 1 Effect of PGE₁, indomethacin and hydrocortisone on B-16 replication *in vitro*. Data represent means of duplicate flasks at each time point; for each determination at least triplicate counts were performed. ▲, Controls; ■, hydrocortisone 10^{-6} M; ○, indomethacin 10^{-8} M; ●, PGE₁, 1 μg ml⁻¹.
Fig. 2 Effect of hydrocortisone on PGE biosynthesis. Data represent total (media + intracellular) concentrations mean ± s.e.m. Each determination was based on duplicate radioimmunoassay determinations on replicate samples. Hydrocortisone: ■, 0 (control); ○, 0.3×10^{-5} M; ●, 10^{-6} M; ▲, 10^{-7} M. Compared with the controls, hydrocortisone produced significant ($P < 0.05$) inhibition of PGE biosynthesis, 63.0%, 45.1% and 57.7%, respectively. Hydrocortisone produced slightly less inhibition of PGF synthesis; the PGE/PGF rates averaged 3.12 in the control experiments and 2.39 in the hydrocortisone experiments.

In an experiment designed to evaluate if hydrocortisone interfered with the cyclo-oxygenase system, homogenates were prepared in which 5×10^5 sonicated cells were mixed with glutathione (55 μg ml⁻¹), hydroquinone (0.55 μg ml⁻¹), EDTA (5.5 μg ml⁻¹), and arachidonic acid (500 μg ml⁻¹) as previously described[12]. After 1 h of incubation at 37 °C in 95% air and 5% CO₂, the homogenates were extracted for measurement of PGE concentrations. In the control conditions, homogenates of 5×10^5 cells synthesised 9.7 ng of immunoreactive PGE. Inclusion of hydrocortisone at a final concentration of 10^{-6} M did not alter PGE synthesis (9.6 ng). On the other hand, indomethacin (10^{-8} M) produced 92.9% inhibition of the conversion of arachidonic acid to PGE₂ (0.74 ng).

In *in vivo* studies, 37 3-week old litter mate female C57BL/6J mice (Jackson Laboratories) were injected subcutaneously with 1×10^6 viable B-16 melanoma tumour cells suspended in 0.2 ml of McCoy's medium containing penicillin and streptomycin but no foetal calf serum. They were divided randomly into control ($n = 19$) and test ($n = 18$) groups and within 2 min received a subcutaneous injection in the same area of 0.1 ml of 0.9% sodium chloride containing either 25% absolute ethanol (control group) or an ethanolic solution containing 5 μg of 16,16-dimethyl-PGE₂-methyl ester (test group). The effect of 16,16-dimethyl-PGE$_2$-methyl-ester on B-16 growth *in vivo*.
*Tumour weights represent wet weights immediately after collection.
†Total cells per tumour was determined by tumour weights × mean cell number per g of tumour in each group.

identical injection procedure was repeated daily. Tumours were apparent approximately 10 d after innoculation in both groups. After 18 d the mice were killed with ether and the tumours were collected and weighed. No necrosis was apparent in any tumour in either group. Tumour cells were separated by passage through a 120 mesh stainless steel grid. After washing twice with medium, the cells were resuspended and counted as described previously. As shown in Table 3, 18 of 19 (95%) mice in the control group developed subcutaneous tumours which weighed an average of 492.8 ± 64.9 mg. In contrast, only 13 of 18 (72%) of the mice in the test (16,16-dimethyl-PGE$_2$-methyl ester) group developed identifiable tumours. Using a χ^2 test, this difference was statistically significant with a P value of < 0.05. Furthermore, among the 13 tumour-bearing animals, the mean tumour weight was 152.0 ± 43.4 mg representing 69.2% inhibition; compared with the mean weight of the tumour-bearing controls, this difference was also statistically different with a P value of < 0.001. Based on the mean number of cells per g of tumour in each group, it was possible to plot the fate of the 10⁶ injected cells. In the control group, the tumours represented an average of 120.6 × 10⁶ ± 17.2 cells per mouse (including the tumour-free animal) whereas in the test group, they represented 20.2 × 10⁶ ± 6.5 cells per mouse. This difference (inhibition by 83.2%) was statistically significant ($P < 0.001$). At the completion of the experiment, the control mice weighed an average of 15.4 ± 0.8 g, and the test group 18.1 ± 1.1 g ($P < 0.05$); there was no correlation between tumour weight and the body weight of the mice.

These studies have further implicated PGE in the control of tumour cell growth. Inhibition of PGE biosynthesis, either by indomethacin or by hydrocortisone results in stimulation of cell proliferation; the effect of both of these compounds can readily be reversed by the addition of small (subthreshhold) amounts of PGE$_1$. The effect of PGE$_1$ in inhibiting proliferation is, in general, dose related. These *in vitro* observations are further substantiated by the *in vivo* experiments, in which subcutaneous (and after the appearance of tumours, intra-tumour) administration of a long-acting PG analogue resulted in significant suppression of tumour growth.

Signal for cell fusion

THE mating of the gametes of *Ulva mutabilis*[1] occurs essentially as described for *Chlamydomonas*[2,3]. When the gametes are mixed, they cluster and agglutinate with the tips of their flagella. Pairs consisting of a (+) and (−)-gamete leave the cluster, the cell bodies are brought together and fusion initiated. In *Chlamydomonas* agglutination apparently creates a signal which triggers the later events of cell wall lysis, mating structure activation and cell fusion[4]. The gametes of *Ulva* lack a cell wall[5] and have apparently no elaborate mating structure[2,5,6]. This note shows that the signal in *Ulva* activates particular areas of the membrane for fusion only for a limited time, and if fusion does not occur then, the ability to fuse is lost permanently.

Figure 1a shows that fusion is finished within 3–4 min both at 10 °C and 22 °C, but that the numbers which fuse are considerably lower at 10 °C than at 22 °C. The data in Figure 1b indicate that the number is constant above 15 °C,

decreases rapidly with decreasing temperature around 10 °C and reaches zero at 0 °C.

The membranes of the two gametes fuse in a region below the flagella and the fused area increases in size as the two gametes merge into each other. The merging is temperature dependent (Fig. 2, insert), and an Arrhenius plot of the initial rate of merging reveals a low activation energy above 15 °C and a higher below 15 °C. The rate most probably depends on the physical state of the membrane, and it is therefore suggested that the membranes change properties around 15 °C. This is also the temperature below which the number of fusers decreases. The decrease can be explained if fusion can take place only for a limited period of time and if the probability for fusion is temperature dependent below 15 °C.

When the two sexes are incubated separately at low temperature for 30–40 min, and mixed after raising the temperature to 22 °C, no reduction in the number of fusers occurs. Consequently the reduction in the ability to fuse develops after the two sexes have been brought together.

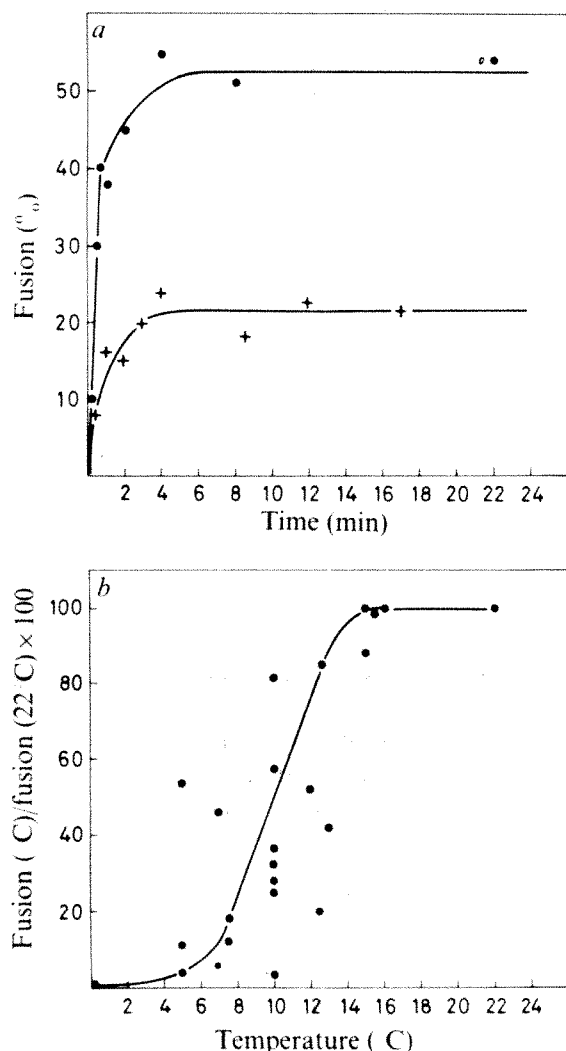
Fig. 1 *a*, The percentage of zygotes formed as function of time at 22 °C (●) and 10 °C (+). The two mating types were mixed at time zero. *b*, The final percentage of zygotes as a function of temperature. The percentage at 22 °C is taken as 100. Gametogenesis was induced as described by Nordby and Hoxmark[12]. The experiments were performed at a cell density of 10^6–10^7 gametes ml^{-1}. At different times after mixing the (–) and (+)-gametes the process was stopped by adding an equal volume of 2.5% glutaraldehyde in 0.2 M cacodylate buffer pH = 8, and 100–400 gametes (*g*) and zygotes (*z*) were counted in the phase contrast microscope. The percentage of fusion is given as $200\ z/g + 2z$.


Fig. 2 Relationship between temperature and the rate of merging. The degree of merging is measured by the length of line A (see insert) and is given as the percentage of the average (*n* = 25) length of the fused gametes ($\frac{1}{2}(B+B^1)$ = B^0). The insert gives the percentages of merging at different times at 10 °C (+) and 22 °C (●). The percentages obtained 1 min after mixing are used as an approximate measure of the initial rate of merging, and such rates are given in the Arrhenius plot. The lines are fitted to the points by the method of the least squares. Above 15 °C the slope is presumably not significantly different from 0, which means zero activation energy. The zygotes were fixed for 4–5 h (see legend to Fig. 1), filtered on to a Nucleopore filter CPRO 1300 0.8 μm, dried by the critical point drying method[13] and coated with Au. The measurements were made directly on the screen of the Jeol ISM-S1 scanning electron microscope (× 10,000), operated at an angle of 0°.

Figure 3 indicates that exposure to 0 °C for only 3–5 min after mixing the gametes reduces the number of fusers to 50%, and exposure for 11 min almost totally prevents fusion.

The effect of cold is simulated at room temperature by cocaine, which is believed to be a membrane stabiliser and prevents virus-induced fusion in mammalian cell strains[7]. When gametes were treated with 5×10^{-3} M cocaine for 15 min, washed three times and mixed immediately, 62% fused. When the gametes were mixed after 5 min and washed after 10 min, the corresponding value was only 2%.

Cocaine at this concentration enables agglutination to occur. Observations also show that at 0 °C the two mating types agglutinate and stay in contact by the tips of their flagella for long periods. It is therefore suggested that this contact starts a process which within minutes makes the gametes incapable of fusion.

To investigate the role of flagellar contact on the fusion process, the flagella were removed with a 15-ml Dounce homogeniser (Pistil B) and the deflagellate gametes mated with biflagellate ones of the opposite sex. The degree of deflagellation could be regulated by the number of strokes, and it appeared that the number of zygotes formed was roughly proportional to the number of biflagellate gametes in the treated sample.

In fixed gametes the flagella stick out from the cell body and their presence is easy to observe. In the zygotes the flagella are directed backwards close to the cell body and it is not always easy to ascertain that all four are present. On inspecting 50 normal zygotes in the phase contrast microscope four flagella were observed in 64%, three flagella in 26%, two flagella in 10% and no zygotes carried one or no flagella. When deflagellated (–)-gametes (no flagella: 73%, one flagellum: 24%, two flagella: 3%) were

Table 1 The effect of con A on pairing

Mating type of the deflagellated gametes	Con A	Mating type of the flagellated gametes	Pairs consisting of: Gametes of the same mating type	Gametes of different mating type	Zygotes	Aggregates
+	+	—	3	70	11	Few
+	—	—	3	78	3	Few
—	+	+	59	0	4	Many
—	—	+	14	51	4	Few

(+) and (—)-gametes were deflagellated with six strokes of the Dounce homogeniser (80% gametes with no flagella, 15% with one flagellum, 5% with two flagella) and pretreated with fluorescent con A (100 µg ml⁻¹)[11], washed four times and then challenged with untreated biflagellate gametes of the opposite sex. The controls were done with untreated deflagellate gametes. Ten minutes after mixing the samples were concentrated in the centrifuge, suspended in 50 µl medium and fixed in 4% formalin. The samples were examined for 10 min each in the fluorescence microscope and the number of pairs and zygotes recorded.

mated with normal (+)-gametes, the corresponding numbers ($n=100$) were 7%, 66%, 21%, 3%, 3%. The high occurrence (66%) of zygotes with three flagella in the experiment compared with the control (26%) indicates that a uniflagellate gamete can participate in zygote formation. If the probability of not observing a flagellum which is present is the same in the experiment and the control, the data also suggest that a gamete without any flagella has a very low chance of fusing.

There seemed, however, to be a tendency for these gametes to pair with others without fusion, as indicated by the preponderance of pairs with two flagella in the experiment above. Four per cent of pairs carried four flagella, 22% carried three flagella, 62% carried two flagella, 12% carried one flagellum and 4% had no flagella. In the pairs the individuals adhere to each other just below the flagella where fusion is normally initiated. When both mating types are deflagellated and brought together with repeated centrifugations many pairs but no zygotes are observed.

In *Chlamydomonas*, concanavalin A (con A) causes isoagglutination of one or both sexes depending on the species[8-10]. In *Ulva*, con A (Sigma) isoagglutinates the flagellate gametes of both sexes at a concentration of 25 µg ml⁻¹ or above, but nevertheless it is possible to reveal a difference between the two kind of gametes. A 50% inhibition of zygote formation is obtained with 4 µg ml⁻¹ con A. The inhibition is due to con A-specific sites at the (—)-gametes, as shown by an experiment in which the gametes were pretreated for 5 min at a concentration of 25 µg ml⁻¹ con A, washed with medium four times, and mixed with untreated gametes of the opposite sex, which had not been treated with con A but had been washed four times. When the con

Fig. 3 The loss of fusion ability with time. The gametes were precooled at 0 °C for 25 min, mixed at zero time and at the times indicated 10 µl of the mixture was dropped on to a slide at room temperature and the percentage fusion recorded 15 min later.

A-treated gametes were mating type (+), the percentage of fusion was normal (experiment 53 control 45%). When mating type (—) was pretreated, only 1% fused.

If deflagellate gametes were treated with fluorescein-labelled con A, it could be demonstrated that pairing of (+) and (—)-gametes was prevented only by con A treatment of the deflagellate (—)-gametes (Table 1). While the flagellate gametes of both sexes are isoagglutinated in the presence of con A, treatment and subsequent washing causes isoagglutination of only the (—)-sex. These observations suggest that the region of the membrane which pairs and later fuses, represents a special part which is different in the two kinds of gametes.

In conclusion, the results can be explained if contact between the tips of the flagella creates a signal which activates a particular area of the membrane of each gamete for a limited period of time. If the two areas, which are different, are brought into contact, there is a given probability for fusion. This probability is dependent on the physical state of the membrane, and decreases with temperature below 15 °C or if membrane stabilisers like cocaine are added. If fusion does not occur during the defined period, the gametes separate and have lost the ability to fuse for good, either because the membranes are irreversibly deactivated or because a new signal cannot be generated.

Recycling of dissolved plasma membrane components as an explanation of the capping phenomenon

IN a recent paper in *Nature*, Bretscher[1] proposed that the capping phenomenon[2,3] is caused by a continuous, directional flow of the lipid components of the plasma membrane across the cell surface from one end to the other, while the membrane proteins remain dispersed by random thermal motion and therefore do not normally participate. Bretscher's explanation of capping is that the cross linking of membrane proteins by attached antibodies and lectins causes them to be swept along by this lipid

current and collected at the "uroid" portion of the cell surface, where he proposes that the membrane lipid is taken into the cytoplasm (by way of a "molecular filter") for return to the opposite side of the cell as cytoplasmic vesicles. In this way Bretscher can account for the selective accumulation into caps of certain classes of surface antigen, without needing to postulate any communication between the surface and the interior. Cross-linked antigens would simply be swept into caps by the lipid current, while uncross-linked antigens would remain dispersed, just as is actually observed.

As an alternative to Bretscher's theory, I propose that capping results from a directional flow of the entire plasma membrane, including not only its lipid but also its integral protein and carbohydrate components. This alternative hypothesis is an extension of the theory previously proposed by Abercrombie et al.[4] to explain fibroblast locomotion and has been developed primarily on the basis of studies of cell locomotion and particle transport[5-7]. The basic postulate of my hypothesis is that all the components of the plasma membrane can dissolve into the cytoplasm at least to a slight extent and that in all motile tissue cells true thermodynamic equilibrium exists between the plasma membrane and its components dissolved in the cytoplasm.

According to LeChatelier's principle of mobile equilibria, forces imposed on the reactants of an equilibrium will cause the equilibrium to shift in whichever direction tends to absorb the imposed force[8]. I propose therefore that local stretching of the plasma membrane should shift this equilibrium in favour of the insertion (assembly) of dissolved membrane components into the plasma membrane. Consequently membrane assembly should be concentrated where the plasma membrane is most stretched. Conversely, membrane disassembly, that is, the dissolving of components back into the cytoplasm, should be favoured wherever the membrane is least stretched. In this way, a steady longitudinal pull applied to the plasma membrane by the cytoplasmic microfilaments would result in reassembly of membrane along the leading margin of the cell, followed by rearward flow of this membrane, with disassembly occurring in the more posterior portion of the cell surface. The disassembled (dissolved) membrane components would then be free to diffuse forward through the cytoplasm back to the reassembly area.

Fig. 1 Diagram of the proposed pattern of plasma membrane movement during lymphocyte capping and tissue cell locomotion. Along the leading margin of the cell, plasma membrane components dissolved in the cytoplasm are rapidly intercalated into the surface (membrane reassembly). The plasma membrane flows rearward from this assembly area, exerting traction against any adhering objects and thereby propelling the cell forward. At the rear "uropod" area of the cell, membrane components re-dissolve in the cytoplasm (membrane disassembly) and diffuse through the cytoplasm back to the front. Bound antibodies, lectins, and so on, are carried to the uropod area by the rearward membrane flow, and being unable to dissolve in the cytoplasm themselves, accumulate there to form caps.
Fig. 2 Diagram of the experiment suggested to distinguish between the membrane recycling theory proposed in this paper and Bretscher's previously proposed theory of directed lipid flow. Lymphocytes are simultaneously exposed to multivalent antibodies against one membrane antigen and to univalent antibodies (Fab fragments) against another of their membrane antigens. The membrane recycling theory predicts that both multivalent and univalent antibodies should accumulate together in the same cap, while Bretscher's hypothesis leads to the expectation that the multivalent antibody should form a cap, while the univalent antibody should remain dispersed.

This directional flow of plasma membrane is envisaged as being responsible for locomotion as well as for capping. Any materials (antibodies, lectins, or small solid particles) which become attached to the surface of a tissue cell undergoing such membrane flow should be carried along to the uroid area of membrane disassembly. Being unable to dissolve in the cytoplasm, these attached materials should remain at the surface, accumulating there to form the familiar "cap". If the attached antibodies and lectins are bound strongly enough to certain components of the membrane, then these components should also be trapped at the surface and accumulated at the cap. Unbound membrane components would, of course, continue to be recycled without accumulating in the cap, though they would pass repeatedly through the disassembly area. In this way my hypothesis can account for the selective accumulation of bound antigens without the need to postulate a molecular filter and also explains why the caps are ordinarily located at the rear uropod area of the cell surface.

The postulate that all components of the plasma membrane, including the lipids, can dissolve into the cytoplasm may at first seem highly implausible or even unacceptable to some readers. Considerable biochemical evidence is, however, accumulating that phospholipids are rapidly interchanged between the several membrane systems of cells. For example, there is rapid equilibration of isotopically labelled phospholipids between mito-chondrial and microsomal membranes[9,10]. This interchange is rapid, reversible and temperature dependent, but does not require metabolic energy, indicating that it represents a true thermodynamic equilibrium. If phospholipids can disassemble from one class of cytoplasmic membrane and reassemble into

another, then it is less surprising that lipid and other membrane components can be disassembled from one part of the plasma membrane and reassembled back into another part of this same membrane, as required by the hypothesis proposed here.

One apparent contradiction to this hypothesis is the observation that univalent antibodies (Fab fragments) and univalent lectins can be bound to lymphocytes without accumulating into caps[2]. However, this observation does not actually contradict the hypothesis because the lymphocytes in question were non-motile and not even attached to a substratum and they were not shown to be simultaneously accumulating other attached materials into caps. If a lymphocyte or other tissue cell could be shown to undergo locomotion without simultaneously accumulating attached materials (even univalent antibodies) into caps, or if cells were shown to cap a multivalent antibody without simultaneously capping a univalent antibody (or lectin) then this hypothesis would be disproved.

How then can one explain the observation that multivalent antibodies do cause capping even on unattached lymphocytes, while univalent ones do not? As a possible explanation, I would suggest that attachment to some sort of surface may be needed for the cell to develop directionality, and to form discrete areas of membrane disassembly and reassembly. In the absence of a solid substratum, the cross linking of the cell surface by multivalent antibodies or lectins may serve as a sort of substitute substratum, stimulating the development of a directional membrane flow and thus capping. This possibility is indirectly supported by the observation of de Petris and Raff[11] that cross linking the lymphocyte surface with multivalent antibodies increases the proportion of cells with discrete uroid tail regions, indicative of cell polarity.

These considerations lead to a pair of experimentally testable predictions regarding the accumulation of univalent antibodies and lectins into caps. The first of these predictions is that even univalent materials should cap if the cells are allowed to attach to a solid substratum and to undergo locomotion. Such caps should form at the trailing margins of the cell. Capping of univalent antibodies on motile polymorphonuclear leukocytes has actually been reported[12] but this experiment does not seem to have been undertaken on lymphocytes. The second prediction is that suspended lymphocytes should cap even univalent antibodies, if their surfaces are simultaneously cross linked by multivalent antibodies or lectins. This should occur even if the multivalent and univalent antibodies are specific for completely different and independent surface molecules. In fact, this prediction can be used to test Bretscher's hypothesis relative to the one that I have proposed above.

According to Bretscher's hypothesis, if multivalent antibodies to one membrane molecule and univalent antibodies to another membrane molecule were simultaneously bound to the surface of the same cell, then the multivalent antibodies should accumulate into a cap, while the univalent antibody should remain dispersed over the cell surface. According to my hypothesis, however, both multivalent and univalent antibodies should accumulate together in the same caps. I would suggest that someone should carry out these experiments.

Lack of effect of naloxone on pain perception in humans

RECENT studies have revealed the existence of endogenous morphine-like compounds in the central nervous system[1-3] and in the pituitary[4]. These compounds, named enkephalin[1] and C-fragment[4], have been reported to produce analgesia when injected intraventricularly in rats and cats[5,6] and to be antagonised by naloxone which is a potent antagonist of narcotic analgesics. They also have a high affinity for the opiate receptor, which has been discovered in the central nervous system of vertebrates including man[7], and they can displace naloxone from these receptors[2-4]. There is substantial evidence that central grey structures in the midbrain are intimately involved in analgesia. Electrical stimulation[8] and microinjection of morphine[9,10] in these regions produce analgesia which is antagonised by naloxone. Stimulation of the central grey region in humans[11] has been reported to produce marked analgesia which is antagonised by small doses of naloxone[12]. In addition, acupuncture analgesia has been reported to be antagonised by naloxone[13]. These findings have led to the hypothesis that there may be an ongoing release within the brain of a morphine-like compound which is partially responsible for pain thresholds. If this were so, then the antagonism of the effects of the endogenous compound by naloxone should affect pain perception. The experiments reported here demonstrate that the perception of experimentally induced pain in normal human subjects is not altered by administration of the opiate antagonist naloxone.

Experiments were carried out on five healthy adult subjects. Each subject was tested on three different days for the effects of intravenous injection of 0.4 mg to 0.8 mg naloxone or a saline placebo, which were administered in a double-blind counterbalanced fashion. Pain was induced by delivering incrementally increasing electric shocks starting at and increasing by 0.2 mA at 1.2-s intervals using a Tursky–Watson type[14] concentric electrode attached to the midpoint of the volar surface of the forearm. The following four parameters were obtained: threshold for sensation, pain threshold, severe pain and maximal tolerance current levels. Subjects were in a semi-recumbent position in a sound-proof room. Respiration rate, skin conductance, heart rate, pulse volume and pupil size were also measured and will be reported in a subsequent paper. The experimental schedule was as follows: 10 min resting and basal recording, one pain test trial session, three consecutive pain trials, 10 min relaxation and basal recording, injection of the drug or placebo and repetition of whole sequence without the trial session.

Figure 1 shows an example of the results obtained from one subject on three different days. The small increase in levels observed after 0.8 mg naloxone is not a consistent finding. These results and those obtained from the other subjects reveal that naloxone does not have a significant effect on any of the four parameters measured in this experiment. The average for the five subjects of the ratios of post-drug level (D) were : 1.06 ± 0.06 (s.d.) for placebo, 1.02 ± 0.18 for 0.4 mg naloxone and 1.03 ± 0.1 for 0.8 mg naloxone.

The lack of effect on perception of pain in our studies suggests that in our experimental conditions there is no significant ongoing release of a morphine-like compound. The amount of naloxone used in our experiments should have been more than adequate to have antagonised any endogenous morphine-like compound present. The dose of 0.4 mg is that recommended to antagonise respiratory depression produced by morphine poisoning and acts within a few minutes[15]. Furthermore, 0.1–0.2 mg naloxone has been reported[12] to significantly antagonise analgesia
Fig. 1 Results from subject showing lack of effect of placebo (*a*), 0.4 mg naloxone (*b*) or 0.8 mg naloxone (*c*), tested on three different days, on sensation threshold (A), pain threshold (B), severe pain (C), and maximal tolerance (D). Each point is the average of three consecutive trials and the actual range of values for each of the trials is indicated by the vertical 'error' bar; these demonstrate the good repeatability of thresholds from one trial to the next on any one day. Where the ranges of the pre-drug (—) and post-drug (- - -) results overlap, one combined line has been drawn.

is that they are not involved with pain mechanisms. This would be very surprising in view of the mass of experiments on animals showing numerous connections between opiate receptor concentrations, enkephalin distribution and analgesia sensitivity to morphine administration. Another possibility is that the endogenous morphine-like compound is released only under special circumstances. The existence of special psychological states when pain is not perceived even when the person is severely wounded is well documented in war and some accidents[18].

produced by brainstem stimulation in man within 10 min of administration. The method we have used for measuring pain thresholds has been reported reliably to demonstrate the analgesic effects of 10 mg morphine[16]. It is true that morphine is used clinically for long lasting pain rather than our brief experimental pain and it is possible that such pains would be more susceptible to modulation by naloxone and an endogenous narcotic. Also in experiments carried out using the same experimental set up (A. El-Sobky, unpublished) used for this study it was found that administration of heroin increased severe pain and maximum tolerance thresholds in heroin addicts. Therefore, it is unlikely that we would have missed any significant effort of naloxone on pain perception. The lack of effect of naloxone on man's pain thresholds which we report here may agree with Goldstein's[17] failure to find a change in rats' avoidance threshold with naloxone.

Since it is unlikely that there is a tonic release of an endogenous morphine-like compound which interacts with pain perception in normal conditions we are left with the problem of explaining the function of opiate receptors and enkephalin in the central nervous system. One possibility

Determination of acetylcholine null potential in mouse pancreatic acinar cells

PERHAPS the most important parameter of transmitter action is the value of the membrane potential at which no potential change occurs after excitation. This value is termed the transmitter null (equilibrium) potential (refs 1 and 2 and refs therein). The determination of this value requires the use of two intracellular electrodes, one for recording the cell membrane potential and the other for passing current to set the membrane potential at appropriate levels. In addition it requires the availability of reproducible short lasting applications of transmitter. The recent demonstration that the pancreatic acinus functions as one electrical unit, that is that unimpaired electrical communication between neighbouring acinar cells exists[3,4], makes it possible to treat the acinus as one cell. By combining insertion of two electrodes into one acinus with local iontophoretic application of acetylcholine (ACh) from a third extracellular microelectrode, we have measured directly the null potential for the action of a neurotransmitter on mammalian gland cells.

Two separate KCl-filled microelectrodes were inserted very close to each other (20–50 μm intertip distance, viewed under Leitz stereomicroscope (×160 magnification)) into surface acinar cells of mouse pancreas *in vitro* as previously described[3].

The tip of a third microelectrode filled with 2 M AChCl was placed close (< 100 μm) to the impaled acinus. The details of the circuits used for membrane potential measurement, intracellular current injection and iontophoretic ACh application have been described in detail[3,5,6]. The composition of the physiological saline solution flowing through the tissue bath was (mM): NaCl, 103; KCl, 4.7; CaCl$_2$, 2.56; MgCl$_2$, 1.13; NaHCO$_3$, 25; NaH$_2$PO$_4$, 1.15; D-glucose, 2.8; Na pyruvate, 4.9; Na glutamate, 4.9; Na fumarate, 2.7. It was gassed with 95% O$_2$, 5% CO$_2$.

Figure 1 shows the simultaneous recording of membrane potential and resistance from two electrically coupled acinar cells. Iontophoretic ACh applications resulted in reproducible potential and resistance changes of exactly the same size and shape in both cells. If currents (d.c.) of varying size were injected through one of the intracellular microelectrodes, the membrane potential, measured with the other microelectrode, could be set at appropriate levels. Figure 2 shows the marked effect of changes in resting potential on the ACh-evoked potential change. The size of the ACh-evoked depolarisation was clearly reduced as the resting potential was diminished and finally reversed into hyperpolarisation at the very lowest level of membrane potential. In the case represented by Fig. 2, the ACh null potential was – 10 mV. In four other tissues, values ranging from – 5 to – 15 mV were obtained.

In the simplest possible model of transmitter action the membrane potential change (ΔV) after excitation is given by

$$\Delta V(t) = \frac{G_s(t)}{G_s(t) + G_0} (e_x - V_m(t)) \quad \text{where}$$

$G_s(t)$ is conductance of activated synaptic region, G_0 conductance of non-synaptic region, e_x transmitter null potential and $V_m(t)$ membrane potential[1]. If one inserts figures for ΔV, G_s/G_0 and V_m taken from experiments like that shown in Fig. 1 (for example, for t corresponding to time of maximal ACh-evoked depolarisation) values for e_x of about – 3 to – 1 mV are obtained. The slight discrepancy between these values and those determined directly (Fig. 2) is a consequence of the slightly nonlinear relationship between ΔV and resting membrane potential at low resting potentials. The directly determined ACh null potential of – 5 to – 15 mV is rather similar to that in the motor endplate[1] where ACh mainly evokes an increase in Na$^+$ and K$^+$ conductance. The ACh-evoked potential and resistance change in pancreatic acinar cells is very sensitive to reductions in extracellular Na concentration[5] and it has been concluded tentatively that the mechanism of action of ACh in the pancreatic acinar cells is to increase Na$^+$ and K$^+$ conductance[1]. The experiments reported here conclusively demonstrate

Fig. 1 Effect of short pulses of iontophoretic ACh application on membrane potential and resistance in two electrically coupled acinar cells. The top part shows the pen recordings, and below is an oscilloscope photograph consisting of two exposures at times marked a and b in the pen recordings. The interruption of the pen recordings represents a 5-min interval. The microelectrode measuring the potential represented in the lower part of the pen recording was inserted first. Subsequently a second microelectrode, through which square wave current pulses could be injected, was inserted. The potential measured by this electrode is shown in the upper part of the pen recording. The short lasting current injections gave rise to short lasting membrane hyperpolarisations, both in the cell into which the current was injected (upper trace) (a circuit was used to compensate for potential changes caused by the current passage through the electrode tip resistance[6], in the beginning of the record the tip resistance compensation is imperfect and is corrected) and in the neighbouring cell (lower trace). The time course of the polarisations is seen in the oscilloscope photograph (calibration: horizontal 20 ms, vertical 10 mV and 2 × 10^{-9} A). The coupling ratio (current pulse-induced potential change in the cell of current injection divided by electrotonic potential change in neighbouring cell) is 1. In the event marker trace in the middle are shown signals marking the periods of ejecting current through the extracellular AChCl electrode. A retaining d.c. current of 2 × 10^{-8} A, to prevent spontaneous leakage of ACh, was used and the ejecting current pulses were of 0.5 s duration and 6 × 10^{-8} A strength.
Fig. 2 Effect of short pulses (constant size and duration) of iontophoretic ACh application on membrane potential recorded at four different values of resting membrane potential. The spontaneous resting potential was −31 mV. Higher and lower resting potentials were obtained by passing d.c. hyperpolarising or depolarising currents, respectively, through a microelectrode inserted into a neighbouring cell. A d.c. retaining current of 2×10^{-8}A was applied to the extracellular AChCl electrode and ejecting current pulses of 0.5 s duration and 6×10^{-8}A size were applied at time of marker signal in bottom trace.

that ACh acts on the pancreatic acinar cell membrane by increasing ion conductance and are consistent with the hypothesis that the ion species involved are Na^+ and K^+.

We thank Mrs M. Gordon for technical assistance and the MRC for grant support.

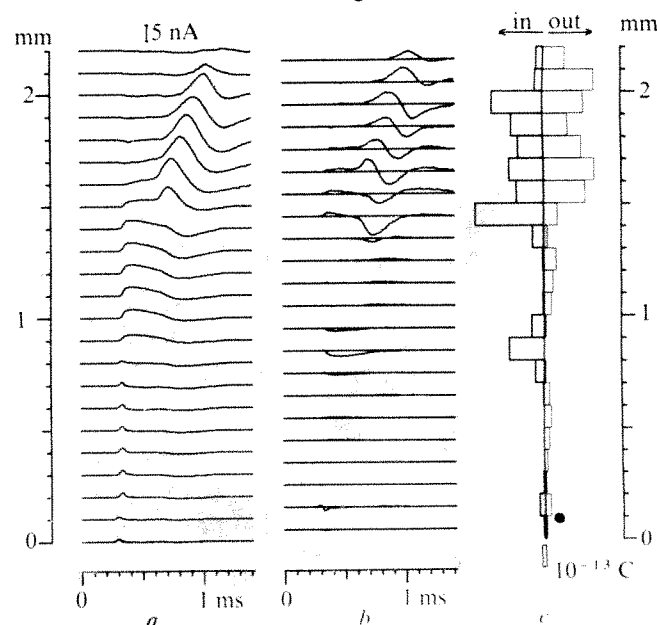
Continuous conduction in demyelinated mammalian nerve fibres

MYELINATED nerve fibres conduct in a saltatory fashion, with sites of inward membrane current restricted to the nodes of Ranvier[1]. Loss of myelin causes long delays in the internodal conduction time, extreme refractoriness and conduction block[2]. In the large rat ventral root fibres studied the slowed conduction always remained saltatory, with discrete sites of inward current, but the limited spatial resolution of the method used prevented conclusions about whether any membrane beyond that of the original nodes was excited. To find out more about the internodal axon membrane exposed by demyelination, we have used an improved technique of external longitudinal current analysis. A smaller electrode separation (120 μm as against 400–600 μm) has improved the spatial resolution[3], and signal averaging has made possible recordings from smaller axons. We have found that in these fibres not only is internodal axon membrane electrically excitable, but that it can support continuous conduction across a demyelinated internode. This result provides a new basis for interpreting the effects of demyelinating disease.

Longitudinal current records from a normal fibre together with their relationships to three nodes are shown in Fig. 1;
Fig. 1 Action currents in normal ventral root fibre, showing saltatory conduction. *a*, Average longitudinal currents (1,024 sweeps) recorded from two platinum wires, 120 μm apart, which were slid 100 μm along the root between averages. The approximate positions of the electrodes with respect to the single active fibre are indicated on the left, with the sites of the nodes of Ranvier inferred from the records. The arrow indicates the direction of propagation of the impulse. *b*, Membrane currents (inward current downwards) obtained by subtracting longitudinal currents as indicated. *c*, Inward (thick line) and outward (thin line) current integrals calculated from (*b*).

the membrane currents were calculated by differencing adjacent longitudinal currents as done by Huxley and Stampfli[1]. Also shown are the time integrals of inward and outward currents at each position, which correspond to the total charge displaced in either direction for each 100 μm of nerve. These records confirm that in normal rat myelinated fibres inward current is confined to the nodes, and

Fig. 2 Action currents in ventral root fibre partially demyelinated with diphtheria toxin, showing stretch of continuous conduction. Explanations of (*a*), (*b*) and (*c*) are as for Fig. 1, but with different scaling.


provides a control for comparison with demyelinated fibres. Figures 2 and 3 are corresponding records for two fibres from animals receiving intrathecal injections of diphtheria toxin 6 d previously, in which the action potentials were propagated in a continuous fashion for about 500 μm. This conduction is termed continuous, because (1), there is a continuous change in latency of the longitudinal currents from one position to the next, in contrast to normal saltatory latency shift, and (2) each 100 μm of nerve in turn becomes a source of inward current, indicating a continuous progression of excitation. The time integrals of inward and outward current reveal that the propagation though continuous, is not even. They also show that at least as much charge crosses the axon membrane in the inward direction along the newly bared internode as at the adjacent nodes.
Fig. 3 Action currents in partially demyelinated fibre, showing stretch of continuous conduction and resumption of saltatory conduction. Explanations of (*a*), (*b*) and (*c*) are as for Fig. 1, but with different scaling.

We have recorded five examples of continuous conduction in fibres with internodal spacings in the range 500–850 μm. In three cases (including the two illustrated) the length of continuous conduction was about 500 μm, and the velocity corresponded to roughly 1/20th of the velocity expected for normal stretches of the same fibre. This figure is similar to the ratio of velocity of continuous conduction in the amyelinated roots of dystrophic mice to normal controls[4,5]. The remaining two cases were of conduction continuous over distances less than 300 μm. Our failure so far to observe such continuous conduction in demyelinated fibres with internodal distances greater than 850 μm (corresponding to an external fibre diameter of about 6 μm), and the previous failure to observe the phenomenon at all[2], indicates some difference between larger and smaller nerves. It is by no means clear, however, that internodal excitability varies with fibre size, since differences in pathology or geometry could also account for the restriction of continuous conduction to small fibres in our experiments.

Epstein–Barr virus genome in infectious mononucleosis

THE seroepidemiological evidence[1] linking the Epstein–Barr virus (EBV) causatively with infectious mononucleosis is compelling, but there are many questions concerning the precise nature of the relationship between virus and disease[2] and the immunological responses that limit the disease[3,4]. For example, until recently it remained unproven that the transforming agent excreted from the throat during acute and convalescent infectious mononucleosis is EBV specific. Lymphocytes from the umbilical cord can be transformed into continuous cell lines by exposure to the virus excreted from the throat. New evidence presented here and data published recently show that such transformed lymphocytes contain EBV genetic material as well as a virus-specific nuclear protein[5] even though such cells, unlike those isolated from the peripheral blood, do not shed virus. Another question, persistent and crucial, has been whether the EBV originally derived from Burkitt's lymphoma in Uganda and the EBV associated with infectious mononucleosis are identical. We show here that the viral DNA in human lymphocytic lines derived from infectious mononucleosis partially lacks homology to EBV DNA. Such differences imply that an extensively deleted, defective EBV genome is retained in lymphocyte lines established from infectious mononucleosis or that the cell lines harbour different strains of EBV with up to 35% heterologous DNA sequences.

Students in the infirmary of the University of North Carolina at Chapel Hill were diagnosed as having mononucleosis on the basis of fever, lymphadenopathy, sore throat, splenic enlargement, atypical lymphocytosis and a positive Monospot test (Ortho Diagnostics). The diagnosis was confirmed by the presence of antibodies to EBV capsid antigen (VCA) and to early antigen (EA) as well as by the other data presented in this communication.

Complementary RNA–DNA hybridisation was carried out on duplicate membranes on which had been immobilised 20–80 μg of the cellular DNA to be analysed. Tritiated EBV-specific complementary RNA (cRNA) that was synthesised *in vitro* on a template of EBV DNA with DNA-dependent RNA polymerase from *Escherichia coli* was hybridised to the denatured cellular DNA as described before[6]. The specificity of the ^{3}H-EBV cRNA and the sensitivity of the test have been defined; as few as two EBV genome equivalents per cell can be detected.

DNA–DNA renaturation kinetics analyses were carried out with EBV DNA tritiated *in vitro* as previously described[7]. The reassociated DNA was distinguished from unrenatured DNA by digestion with S1 single-strand-specific exonuclease derived from *Aspergillus oryzae* as described before[6]. We express results as C_0t values (mol s l^{-1}) in which C_0 is the concentration of double-stranded DNA; estimates of EBV genome numbers were based on the $C_0t_{\frac{1}{2}}$ values[6].

In Table 1 are some of the data from a series of patients with proven mononucleosis. Lymphoblastoid cell lines were established from the peripheral blood of the patients after 3–4 weeks of culture *in vitro*. In addition to EBV capsid and early antigens, each of these cell lines contained EBV DNA as shown by cRNA–DNA hybridisation.

Filtered throat washings from the same patients when applied to umbilical cord leukocytes regularly led to the establishment of lymphoblastoid cell lines. Cord lymphocytes fail to proliferate if they are not exposed to the throat washings[8]. These transformed cells do not contain capsid or early antigens (refs 10 and 11 and Table 1). The hybridisation data show that there is EBV genetic material in the cell lines which suggests the

virus-specific nature of the transformation. Such cells also contain EBV nuclear antigen (EBNA)[10]. The relative number of genome equivalents found in the lines is consistently less than that found in peripheral blood cell lines. Explanted peripheral blood cells sometimes contain large numbers of EBV genomes

Fig. 1 Incomplete homology to the EBV genome of the viral DNA sequences in lymphocyte lines from infectious mononucleosis. Determinations were made by DNA–DNA renaturation kinetics analysis. *a*, ×, ^{3}H-EBV DNA (0.02 µg) + calf thymus DNA (2 mg); ○, PB20 DNA (1.1 mg) was from a cell line derived from peripheral blood; ●, TW20 DNA (1.8 mg) was a cord lymphocyte line transformed by throat washings from the same patient; □, HR1K DNA (2 mg) was homologous DNA from the EBV-producing cell line that was the source of the index EBV DNA. *b*: △, PB16 DNA (1.5 mg) was from a cell line established from the peripheral blood of another patient with infectious mononucleosis; ▲, TW16 DNA (1.5 mg) was from a cell line produced by exposure to throat washings from the same patient. Other symbols as in (*a*). Labelled EBV DNA (0.02 µg, specific activity 1.8×10^6 c.p.m. µg^{-1}) was present in all renaturation mixtures. The total concentration of DNA in all mixtures was brought to 2 mg by addition of calf thymus DNA before denaturation and reannealing.

and may even replicate virus[12]; this does not occur with the transformed cord cell lines.

Finally, virus shed from one of the peripheral blood cell lines (PB6) could transform cord blood lymphocytes. The secondarily transformed cells also contained a relatively small amount of EBV DNA, but no detectable capsid or early antigens. This last finding indicates that peripheral lymphocytes when transformed into cell lines can shed biologically active EBV.

Perhaps not all the DNA sequences found in the genome of the standard lymphoma-derived P3HR1 virus[13] exist in the mononucleosis cell lines. Another possibility is that the cord blood lymphocytes, which contain fewer copies of viral DNA and do not express viral structural antigens, do not contain as full a representation of the EBV genome as the cell lines derived from peripheral blood.

Figure 1 shows an analysis of the DNA extracted from pairs of lymphoid cell lines, one from peripheral blood (PB), and one from cord blood cells that had been transformed by throat washings (TW). Each pair of cell lines, PB and TW20 and PB and TW16, derive from materials from a single patient. We found that neither of the peripheral blood cell lines contained all the viral DNA sequences of the prototype EBV genome. The PB20 cells lacked 30–35% of the homologous viral DNA, and the PB16 line lacked 25–30% of the homologous sequences found in the index viral DNA. Nevertheless, both of these cell lines did produce EBV capsid antigens and early antigens. This means either that the whole of the EBV genome is not needed for the coding and translation of these antigens, and that the genome is defective, or that full or unit-length viral DNA is present in the two lines, but that 25–35% of this viral genome contains heterologous DNA sequences.

Another conclusion from these data is that cord blood lymphocytes transformed by the throat washings contain approximately the same viral DNA sequences as are found in the cell lines derived from peripheral blood. Apparently the cord blood lymphocytes do not necessarily select for defective genome. The reason for the sharply restricted expression of the genome contained in the cord cell lines is therefore not apparent.

Cord cells transformed by cell-free extracts from a peripheral blood cell line (PB6) contained about 80% of the DNA sequences found in the index viral genome (Fig. 2*a*).

Figure 2*a* shows the results of analysis of the DNA of EBV-transformed marmoset cells. This line originated from marmoset lymphocytes that had been transformed by throat washings obtained from a patient with infectious mononucleosis[14]. Here approximately 40% of the DNA sequences found in the P3HR1-derived virus are not present in the marmoset line.

An analysis of Raji DNA is also shown (Fig. 2*b*). The completeness of reannealing of the homologous DNA approaches 100%. This is expected as Raji cells are thought to contain unit-length viral DNA[15] and can be induced with IUdR to make virus[16].

Understanding of the pathogenesis of infectious mono-

Fig. 2 Extent of homology of the viral DNA sequences found in various lymphoblastoid cell lines. *a*, △, B95–8 DNA (2 mg) was from a marmoset cell line transformed by human EBV; ▽, PB6 DNA (1.3 mg) was from a human cord cell line transformed by virus from a cell line established from the peripheral blood of a patient with infectious mononucleosis; ×, ^{3}H-EBV DNA; ■, Raji DNA; □, HR1K DNA. *b*, Three concentrations of Raji DNA (1, 0.42 mg; 2, 0.56 mg; 3, 0.84 mg), a human lymphoblastoid cell line derived from an African Burkitt's lymphoma; these cells contained fully homologous EBV DNA. ●, ^{3}H-EBV DNA; ○, HR1K DNA (2 mg).

nucleosis is still deficient. The virus apparently replicates somewhere in the oropharynx, including perhaps the parotid gland[17]. The precise site and cell type in which the virus replicates, however, are not known.

Earlier analyses[8] suggested that all the P3HR1 EBV DNA sequences were present in three different IM cell lines, but our results obtained with different cell lines show clear differences. Up to 35% of the EBV DNA sequences were missing in cell lines established from peripheral blood as well as in cord blood cells transformed with fresh virus isolates. We do not know whether the molecular weight of the homologous DNA in the cell lines was 35% less than that of virion DNA. Defective genomes might be more liable to persist in lymphocytes, although clearly some lymphocytes contain replicative amounts of genome; explantation of peripheral blood cells can lead to shedding of virus.

In the case of the B95-8 virus, a fuller analysis has been possible. Pritchett *et al.*[18] showed that this virus lacked at least 15% of the DNA sequences found in the P3HR1 EBV, yet the molecular weight of the B95-8 virus DNA was the same as that of EBV. The missing sequences were thought to be made up of repetitions of DNA sequences found in EBV; no heterologous sequences were detected.

Are there strain variants of EBV? The missing sequences in EBV associated with infectious mononucleosis may be replaced by heterologous DNA sequences so that there are different strains of EBV bearing extensive but not complete homology to the EBV derived from an African lymphoma. Epidemiologi-

cally and pathogenetically this is an attractive possibility as brought out recently by Miller *et al.*[11], but we cannot distinguish such heterologous viral DNA sequences because of the lack of any other EBV strain in the quantity needed for reciprocal homology studies.

Nasopharyngeal carcinomas also contain viral DNA only partly homologous to EBV[19]. Recent analysis of herpes simplex type 1 and type 2 DNA by restriction endonuclease digestion and similar analyses of cytomegalovirus DNA demonstrate the existence of numerous strains of these viruses hitherto undefined[20-22]. The biological significance of this diversity is undetermined. In the case of herpes simplex virus both defective genomes and strain variants exist, and we believe this will prove to be the case with EBV, but we are not yet ready to refer to the Epstein–Barr "viruses".

We thank Drs James McCutchan and James Taylor of the Student Infirmary of the University of North Carolina for making this work possible. We also thank the students who participated and the infirmary physicians who cooperated. We thank Drs Lindsey Hutt, Harry Dascomb and Stanley Lemon for helping in the study of some patients. Photoreceptor membrane carbohydrate on the intradiscal surface of retinal rod disks

RHODOPSIN is an integral constituent of the photoreceptor membrane where it is believed to function as a light-activated gate for the release of ions or other substances. The shape, localisation and orientation of the rhodopsin molecule in the membrane is therefore of great importance in understanding the primary events of light perception. Uncertainties in the present state of knowledge are reflected in the numerous models which localise rhodopsin variously on the internal, external or both sides of the disk membrane. In the last few years it has become increasingly accepted that rhodopsin is an elongated molecule, partially embedded in or entirely spanning the disk membrane. Even this model leaves many uncertainties
Fig. 1 *a*, Detail of a rod outer segment from a formalin–glutaraldehyde-fixed and Vestopal-embedded frog retina. Carbohydrate reaction (periodic acid-thiosemicarbazide-silver proteinate[11]) was carried out on thin sections. The dense reaction product is seen inside the membrane loops of the disk margins (dark dots, arrows) whence it can be traced as a thin dense line into the interior of the disks delineating the contact (intradiscal) surface of the membranes (double arrow). *b*, Control section from the same material without oxidation with periodic acid. No reaction can be seen inside the disks.

as to the orientation of the molecule in the membrane. Besides the chromophore retinal, the oligosaccharide chain[1,2] is a good orientation point on the rhodopsin molecule. Since rhodopsin is the dominant protein of the photoreceptor membrane[3–8] where it forms about 85–95% of the total protein content, localisation of the carbohydrate component of the membrane would indicate the location of the rhodopsin carbohydrate moiety. Here I present an electron microscopic histochemical demonstration of the carbohydrate component of the photoreceptor membrane; a part of this investigation was reported briefly earlier[9].

In the first group, aldehyde-fixed retinae of frogs (*Rana esculenta*, *Rana pipiens*) were embedded in Epon, Vestopal or glycol methacrylate and electron microscopic histochemical reactions for detection of carbohydrates were carried out on thin sections. Three reactions were based on oxidation of vicinal glycols to form aldehyde groups that were subsequently demonstrated by silver methenamine[10], thiosemicarbazide-

silver proteinate[11] or alkaline bismuth[12]. Oxidation was omitted in the controls. In addition, the carbohydrate staining by phosphotungstic acid at low *p*H (refs 13 and 14) was used because of the better resolving power of the method. All electron microscopic histochemical reactions, from which a representative example is shown on Fig. 1*a*, demonstrated a fine reactive line at the contact (internal) surface of disk membranes. The reaction was especially obvious at the disk margin where it was localised at the internal surface of the membrane loop. The reaction was absent in the control specimens (Fig. 1*b*).

In the second part of this work, ferritin-labelled concanavalin A (con A–Ft) was used to detect lectin-binding carbohydrates on the photoreceptor membrane. The con A–Ft was prepared according to de Petris *et al.*[15] and was a gift of Dr D. Lawson (University College, London). A major difficulty in lectin binding was the inability of the voluminous conjugate to penetrate across plasma and disk membranes that was necessary to expose both sides of the photoreceptor membranes to the lectin. The problem was largely solved by a freeze–thawing method as detailed in the following:

Fig. 2 Ferritin-labelled concanavalin A (con A–Ft) is bound to the internal surface of disk-derived vacuoles. No conjugate can be found at the external surface of the vacuoles. This detail represents a portion of an outer segment from a frog retina that was swollen in ammonium acetate, fixed, freeze-fractured and exposed to con A–Ft.

isolation of frog retinae
↓
swelling in 20 mM ammonium acetate (*p*H 6.9, 4 °C, 15 min)
↓
fixation in 0.5% glutaraldehyde (in 10 mM cacodylate buffer *p*H 7, 4 °C, several hours)
↓
washing in buffer (20 mM cacodylate, 4 °C, 20 h)
↓
freezing in liquid nitrogen and breaking the retinae into little fragments
↓

thawing in con A–Ft solution   thawing in buffer (4 °C, 15 min)
↓   ↓
washing in buffer   20% glycerol in buffer (4 °C, 2 h)
↓   ↓
fixation in osmium   freeze-fracturing to check the sidedness of the membranes
↓
embedding for electron microscopy

Freeze-fracturing was made in a modified freeze-fracturing device (P. R. Környei and Balogh, to be published) that was based on the cold block principle.

The unilateral localisation of carbohydrates was even more unambiguous with the con A–Ft binding than with the histochemical reactions. The swollen disks appeared as more-or-less

inflated vacuoles. Those disk-derived vacuoles which became patent because of the freezing, fracturing and thawing, contained the con A–Ft bound to the internal (intradiscal) surface of the disk membranes (Figs 2 and 4). No con A–Ft particles were ever found associated with the external (interdiscal, cytoplasmic) surface of the disks, although it was freely accessible to the conjugate because of the broken plasma membrane. The latter showed con A–Ft particles bound to its extracellular surface. No binding was observed using α-methyl-D-glucoside together with the lectin.

It is crucial for evaluating the con A-binding experiment whether the original sidedness of the disk membranes has been retained or not. One way to check this is the known asymmetrical distribution of intramembrane particles on freeze-fractured photoreceptor membranes. As can be seen in Fig. 3, the sidedness of the disk membranes was not altered during the preparative procedure since, similarly to intact disk membranes,

Fig. 4 The same material as Fig. 2 to show persisting disk edges in the con A–Ft experiment (arrows). The membrane loops of the disk edges are directly continuous with the interior of the disk-derived vacuoles indicating the original sideness of the disk membranes.
Fig. 3 Freeze-fracture image of swollen disks, treated similarly to those in Fig. 2 (without con A–Ft). The presence of numerous intramembrane particles on fracture face looking towards the lumen of the vacuoles (fracture face of "cytoplasmic" membrane half, PF) indicates that the original sidedness of the disk membranes has not been changed during the preparative procedure. EF, fracture face of the endoplasmic membrane half.

the majority of intramembrane particles was found on fracture face looking towards the interior of the vacuole ("cytoplasmic" membrane half, fracture face PF[16]). Another means of recognising the sidedness of the membranes is the known rigidity of the disk edge which preserves its form even after drastic treatments[17,18]. In our con A–Ft material, disk edges were often observed and their concavity was continuous with the internal space of the disk-derived vacuoles (Fig. 4, arrows). This observation indicates that the disks were only swollen and not everted during the preparative procedure.

Both the carbohydrate reactions on ultrathin sections and the con A–Ft binding on freeze-thawed photoreceptor outer segments showed the presence of a carbohydrate layer at the intradiscal surface of frog retinal rods. The extraordinary molecular simplicity of photoreceptor membranes makes it easy to find the most probable candidate for the carbohydrate layer. Rhodopsin is known to be the dominant protein in outer segment membranes[3-8] (about 9/10 of all membrane proteins being rhodopsin). It is a glycoprotein[1,2] and binds concanavalin A strongly and specifically[19,20]. There can be little doubt therefore that of the proteins present in rod outer segment membranes, rhodopsin is primarily responsible for the lectin binding. The contribution of membrane glycolipids to the carbohydrate reaction seems to be negligible, partly because of the low percentage of glycolipids when compared with the rhodopsin content and partly because an intradiscal carbohydrate reaction was present also in our embedded material. But even if we assume a small contribution of glycolipids to concanavalin-binding, it does not make
localisation of the rhodopsin carbohydrate moiety on the internal disk surface doubtful due to the unilateral localisation of the lectin-binding sites.

Assuming that rhodopsin is responsible for the carbohydrate reaction, the carbohydrate component of rhodopsin must be localised at the intradiscal surface of the disk membrane. This means that the rhodopsin molecule is either situated in the internal half of the membrane or spans the membrane with its extended oligosaccharide chain[21] protruding into the intradiscal space. Such a localisation of the rhodopsin carbohydrate moiety is supported by observations in which it was shown that the carbohydrate component and the chromophore were not accessible to protease digestion in photoreceptor vesicles, although more than one third of the rhodopsin molecule was digested[22,23]. At present, it is difficult to compare the present findings with investigations[20,24] reporting concanavalin binding on the external surface of isolated disks. To correlate the contradicting results it would be necessary to know whether the photoreceptor vesicles in the cited experiments were completely closed and whether all vesicles showed the original sidedness.

Role of nucleotide hydrolysis in microtubule assembly

MICROTUBULE assembly *in vitro* requires (in normal conditions) that GTP be bound to the exchangeable nucleotide-binding site of tubulin[1-3]. The bound GTP is hydrolysed during polymerisation and the resulting GDP remains bound to the microtubule while the phosphate is released into the medium. Although hydrolysis normally occurs during polymerisation, microtubules will form in a non-hydrolysable analogue of GTP, guanylyl imidodiphosphate (GMP-PNP)[4-6]. We have observed[6], as also has Arai[5], that microtubules polymerised in GMP-PNP are not depolymerised by concentrations of Ca which completely depolymerise GTP microtubules. We have now found that GMP-PNP microtubules do not display evidence for a rapid equilibrium between polymer and subunit. The irreversible behaviour of GMP-PNP microtubules may explain the insensitivity to Ca and suggests a function for nucleotide hydrolysis during tubulin polymerisation.

The reversibility of polymerisation was studied by dilution of preformed microtubules while constant solvent conditions were maintained. As others have observed[7-9], a plot of the extent of polymerisation in GTP against total tubulin concentration intercepts the concentration axis at about 0.2 mg ml[-1] (Fig. 1). This concentration has been referred to as the "critical concentration" and is the minimum concentration at which the polymer (microtubules) exists. According to the theory of Osawa and Kassai[10], the critical concentration is the point at which the first turn of the polymer helix is stable and can act as a nucleation structure for further growth. The mechanism of microtubule assembly is not known, but it is likely to be much more complicated than the simple condensation mechanism of Osawa and Kasai's theory. Thus the use of the term "critical concentration" does not imply here any specific model of polymerisation. The observation of a non-zero critical concentration, however, is important because it indicates that below this concentration no microtubules exist. In the dilution experiments this can only mean that the microtubules break down

Fig. 1 Dilution series of GTP and GMP-PNP microtubules. Microtubes were assembled at 35 °C in 0.1 M MES buffer (morpholino ethanesulphonic acid) at *p*H 6.6, 1 mM EGTA, 0.5 mM MgCl$_2$ and either 1.0 mM GTP or 1.5 mM GMP-PNP (concentrations at which maximum velocity of polymerisation is observed without inhibition). After an apparent plateau level of polymerisation had been achieved, the sample was diluted with the same buffer and the new turbidity level was determined after 5 min. Tubulin was prepared by three cycles of polymerisation and centrifugation in 25% glycerol. After the last centrifugation the pellet was resuspended in buffer and passed through Sephadex G-25 to remove most remaining traces of glycerol and nucleotide. ○, GTP microtubules; ●, GMP-PNP microtubules.

as the protein concentration is lowered, and therefore that they are in reversible equilibrium with subunits (or small aggregates). The complete breakdown of GPT microtubules after dilution has been confirmed by electron microscopy.

When GMP-PNP microtubules are subjected to the same dilution experiment, the data points lie on a straight line with an intercept on the concentration axis which is indistinguishable from zero (Fig. 1). In eight experiments at temperatures between 20 and 37 °C the average intercept was −0.07 mg ml[-1] and in no experiment was the intercept greater than zero. The failure of GMP-PNP microtubules to break down at very low concentrations up to 1 h after dilution has been confirmed by electron microscopy. At temperatures below about 18 °C GMP-PNP microtubules become reversible and Ca sensitive and the concentration curve has a positive intercept. At these lower temperatures the critical concentration of analogue tubules is always less than that of GTP tubules.

Although microtubules formed in GMP-PNP seem to be irreversible, or nearly so, complete polymerisation of tubulin is not observed in the analogue. The "plateau" level of polymerisation in GMP-PNP was always less than in GTP, although the difference varied widely between preparations. The lower level observed in the analogue is probably a result of inhibition of polymerisation by residual amounts of GDP remaining in the preparation. It is also possible that only a fraction of tubulin subunits are capable of polymerisation in GMP-PNP. Neither of these explanations alters the conclusions reached about the properties of GMP-PNP microtubules.

The polymerisation of tubulin and of muscle actin (and most cytoplasmic actins) requires bound nucleotide (ATP or ADP in the case of actin). In both proteins the bound nucleotide triphosphate is hydrolysed during polymerisation, and in both systems the non-hydrolysable imidodiphosphate analogue promotes polymerisation[11]. The role of bound nucleotide in actin polymerisation has been studied extensively but no clear concensus exists concerning the function of hydrolysis in polymerisation. It has been suggested that hydrolysis is involved in the depolymerisation reaction of actin[12] but the most direct test of this idea, depolymerisation of AMP-PNP F-actin by dilution, has not been performed successfully[11].

In the experiments reported here we have demonstrated that microtubules assembled in GMP-PNP are essentially irreversible and that hydrolysis of bound GTP probably promotes the depolymerisation of microtubules. By analogy, it is reasonable to assume that ATP hydrolysis has a similar function in actin polymerisation. The possible benefit of this to the living cell in regulating polymerisation of fibrous structures is apparent. By using the energy of binding of nucleotide triphosphate, rapid assembly can be obtained. Rapid polymerisation, however, may be incompatible with the need to disassemble rapidly the polymer later (such as during mitosis). Hydrolysis is thus used to produce a more readily depolymerisable state. It has been observed clearly in the case of microtubules and is probably also true of actin fibres that various degrees of stability of the polymer exist in the cell. At least some of this variation could be achieved by maintaining the bound nucleotide as the triphosphate. This could be done by the action of a nucleotide diphosphokinase ("transphosphorylase") such as has been observed as a component of tubulin preparations[2,6]. Future observations on the state of bound nucleotide in stable compared with labile microtubules and microfilaments may determine whether these speculations are valid.

Protein evolution in cyanobacteria

THERE has been a great deal written in recent years on evolutionary relationships between prokaryotes and eukaryotes[1,2], and the possible origin of photosynthesis in eukaryotic cells by endosymbiosis of a cyanobacterium[2,3]. Molecular methods have been used in an attempt to elucidate the principal events in Precambrian cellular evolution. For example primary structures of plastocyanin[4], cytochrome f[5], and ferredoxin[6,7] have been published. These sequences have been compared to primary structures of functionally analogous macromolecules from eukaryotes. Before conclusions on the evolutionary relationships between prokaryotic cyanobacteria and eukaryotic algae and plants can be made from one representative amino acid sequence, it is necessary to evaluate the amount of amino acid sequence variation in proteins isolated from a wide range of cyanobacteria. In this study the amount of variation in plastocyanins and in cytochromes f was investigated. The results from complete and partial amino acid sequence determinations on these proteins from a number of cyanobacteria, suggest that the rate of evolution of the proteins in oxygenic photosynthetic prokaryotes is much less than the rates of evolution of corresponding proteins in eukaryotic algae and higher plants.

Plastocyanin and cytochrome f are components of the photosynthetic electron transfer chain[8]. Cyanobacteria were chosen which were reasonably diverse but also suitable to culture in the laboratory. The cytochromes f were from *Anabaena variabilis*, Kützing; *Plectonema boryanum* 1462/2 (also called *Phormidium luridum* var. olivaceum) and *Synechococcus* 6312. The first two are filamentous cyanobacteria and the third is unicellular. The nucleotide base compositions of these strains are 44% (ref. 9), 47% (ref. 9), and 50.2% (ref. 10) G + C respectively. The G + C content of *Spirulina maxima* was 36.6% (M. Herdmann, personal communication) measured on a sample of dried cells from the source in ref. 5. Plastocyanin from *P. boryanum* was also investigated. *A. variabilis* and *P. boryanum* were generally cultured in modified medium C of Kratz and Myers as described previously[4]. *P. boryanum* was also grown in the medium of Allen and Arnon[11] and latterly in the medium of Cannon *et al.*[12]. Cells of *Synechococcus* 6312 were a gift from R. Y. Stanier.

Isolation of the proteins was, in the initial stages, as described previously[4,13,14]. After ammonium sulphate fractionation of the cell extract and desalting to 1 mM phosphate buffer, pH 7, the solutions were passed down DEAE-cellulose where only *Synechococcus* 6312 cytochrome f was absorbed. Cytochromes f and plastocyanins from the other strains were absorbed on to CM-cellulose in the same buffer. The proteins were eluted from the ion-exchange celluloses with buffers of increased ionic strength. The proteins were further purified by absorption on to CM-cellulose at pH 3.9 followed by elution at increased pH and by gel filtration on Sephadex G-75. The protein preparations were checked for purity by polyacrylamide gel electrophoresis[15]. Later *Synechococcus* 6312 cytochrome f and *A. variabilis* plastocyanin were run in 8% sodium dodecyl sulphate (SDS) gels[17]. *A. variabilis* plastocyanin ran partly as a dimer after incubation with SDS in mild conditions although it ran as a monomer during Sephadex gel filtration with phosphate buffers. This phenomenon has been reported for spinach and *Scendesmus plastocyanin*[17].

Cytochrome f has been isolated from all cyanobacteria investigated so far in this laboratory but the preparation of plastocyanin has proved much more difficult. No plastocyanin was detected in *Synechococcus* 6312 including one preparation using 500 g fresh weight of cells. Attempts to prepare plas-

tocyanin on a small scale from another two strains of *Synechococcus*, 6307 and *Anacystis nidulans* (*Synechococcus* 6301)[10] and two strains of *Aphanocapsa* (unicellular cyanobacteria) were unsuccessful. A number of attempts to isolate plastocyanin on a large scale from *S. maxima* were also unsuccessful. Initial results of an immunological survey of the culture collection of R.Y. Stanier at Institut Pasteur (my unpublished results) have indicated the presence of plastocyanin in crude extracts of all heterocyst forming cyanobacteria investigated. Extracts from three unicellular species (2 *Aphanocapsa* and 1 *Microcystis*) and a few *Phormidium* and *Pseudoanabaena* species show definite cross reaction but tests on a large number of non-heterocyst forming filamentous cyanobacteria (including a species of *Spirulina*) and unicellular species proved negative. There was no immunological cross reaction with an extract of *A. nidulans* although the presence of plastocyanin in this strain has been suggested on the basis of electron paramagnetic resonance signals[16].

The amounts of the proteins isolated were generally very small for sequencing purposes (normal yields were a few mg from 1 kg fresh weight of cells). The sequence information was obtained from proteins isolated from cultures grown over a two-year period. In addition the gifts of some *Synechococcus* 6312 cytochrome f from G. Cohen-Bazire and *A. variabilis* cytochrome f from D. W. Krogmann were received.

P. boryanum cytochrome f was prepared in considerably higher yield (about 20 mg from 650 g fresh weight cells) from a batch grown in the medium of Cannon *et al.*[12], which contains 10–50 times more iron per l than most cyanobacterial media. This success could not be repeated. In an attempt to increase the yield of cytochrome f, batches of *A. variabilis* were grown in the presence of diphenylamine (12 mg l⁻¹) in modified Detmer's medium[19]. The strain did not grow well in these conditions and much lower yields of cells resulted, although the proportion of cytochrome f was increased. The copper content of the cyanobacterial plastocyanins, estimated with bathocuproine[20] indicated the presence of 1 mol Cu per mol protein.

Native oxidised plastocyanin and native reduced cytochrome f were degraded in a Beckmann, model 890 A automatic sequenator by a 70 min 'Quadrol' double cleavage programme[21]. All three cytochromes f tended to wash out of the cup and yields of phenylisothiocyanate derivatives dropped quickly. Identifications proved impossible after 20 cycles. Cytochromes f from *Synechococcus* 6312 and *P. boryanum* were later degraded using a single cleavage programme with dimethylbenzylamine[22]. Identification of phenylisothiocyanate derivatives was carried out as described previously[4] with the addition that some derivatives were hydrolysed to the free amino acids with HCl[23]. The criteria of reliability of sequenator results adopted were generally those of Niall[24].

Euglena gracilis	43	42	35	35	—	39
Alaria esculenta	47	49	45	67	39	—

For the comparison Asx is taken as identical to both Asp and Asn, and Glx to both Glu and Gln.

• terminal regions of the cytochromes *f* were confirmed by digestion of small amounts of the cytochromes with trypsin after removal of the haem. The rest of the available material (about 8 mg) was used. Peptides were isolated by established methods for prokaryotic type *c* cytochromes[25]. Yields of tryptic peptides from many parts of the sequences were very low or zero partly due to the presence of –Asn–Gly– sequences which readily undergo deamidation[25].

The alignment of the amino-terminal regions of the cytochromes *f* is shown in Fig. 1. The other parts of the sequences from which peptides were obtained and sequenced are aligned by homology with the complete sequences of *P. boryanum* cytochrome *f* (my unpublished results); *Porphyra tenera* cytochrome *f*[26] and the other prokaryotic and eukaryotic cytochromes *f* aligned previously[4].

The similarity matrix (Table 1) shows that *P. boryanum* and *Spirulina maxima* cytochromes *f* have nearly identical percentages of similarity to each eukaryotic algal sequence taken in turn. The cyanobacterial sequences are 10% closer to each other than the average for all the other sequence comparisons. They are much closer to the red algal (*P. tenera*) cytochrome *f*[26] than to the other eukaryotic algal cytochromes. This is interesting in view of the many close similarities between cyanobacteria and red algae[27]. The partial sequences of the other cytochromes *f* strongly suggest that these numerical relationships are general.

The amino terminal sequence of *P. boryanum* plastocyanin is aligned in Fig. 2 with those of *A.variabilis* plastocyanin[4], *Chlorella fusca* plastocyanin[18] and two examples of higher plant plastocyanins[29,30]. The partial sequence of plastocyanin

from *P. boryanum* has considerable similarity to the same regions in the other plastocyanins if a deletion at position 13 is considered. Gly-34 (one of the tentative assignments), Val-33 and Met-7 have previously been invariant residues. The similarity matrix (Table 2) gives percentage comparisons between the amino-terminal sequences. This region of *A.variabilis* plastocyanin is slightly closer to the eukaryotic algal plastocyanin than to *P. boryanum* plastocyanin. This finding is valid even if the changes in the previously invariant residues are treated with caution.

Amino acid sequences of cyanobacterial ferredoxin from *Aphanothece* and two strains of *Spirulina*[6,7] have been compared to primary structures of ferredoxins from eukaryotic algae and plants. Results were obtained similar to those in the present study. The prokaryotic sequences are either not closer or only slightly closer to each other than to the corresponding eukaryotic algal sequences. Where comparisons with higher plant sequences can be made (in the cases of plastocyanin and ferredoxin) cyanobacterial primary structures do seem to be closer to each other than to the higher plant sequences. Ferredoxin sequence comparisons ought to be treated with caution because multiple ferredoxins with quite distinct amino acid compositions have been shown to be present in some plants[8] and in cyanobacteria[31,32].

Fossil evidence indicates that filamentous and unicellular forms of cyanobacteria diverged in the early Precambrian era, about 3×10^9 yr ago[33] and many of these have subsequently evolved little. In the Gunflint Iron formations (1.6×10^9–2×10^9 yr old) many representatives of extant cyanobacterial families (Chroococcaceae, Oscillatoriaceae and Nostocaceae)

have been identified[22]. In more recent rocks (the Bitter Spring formations, 0.9×10^9 yr old) many species of cyanobacteria have been identified at the specific or generic level with extant organisms, including *Spirulina*. If the strains of cyanobacteria for which protein sequence information is available are as evolutionarily diverse as the fossil record suggests, then it is perhaps surprising that their amino acid sequences are not more different. Cyanobacteria were a diverse group of organisms 3×10^9 yr ago[33] and eukaryotic algae diverged in a time measured in hundreds of millions of years[33]. There seems to be, however, the same degree of similarity in analogously functioning proteins. It has been postulated that the rate of evolution of a particular protein in a wide range of organisms is approximately constant[34]. This has been shown for cytochrome *c*, haemoglobin and fibrinopeptide and has enabled phylogenetic trees to be constructed which correspond well with palaeontological evidence[34]. If cyanobacteria have evolved very little[33] in morphology and physiology since the oxygenic mode of photosynthesis was established in the Precambrian era there is probably little selective value for changes in primary structure of their photosynthetic proteins. Chloroplasts have evolved and diverged in a wide variety of eukaryotes over a much shorter time span than that in which cyanobacteria have

continued to populate similar ecological habitats. The rate of evolution of cytochrome *f* (a type *c* cytochrome) could be expected to be comparable to that of mitochondrial cytochrome *c* which is three "accepted point mutations" per 10^8 yr (ref. 34). The rate of evolution of higher plant plastocyanin is about twice this value[35]. At these rates of change of amino acid sequence one would expect very little remaining similarity in primary structure of these proteins from diverse blue-green algae (except for a few highly invariant amino acid residues required for a specific function such as binding of the prosthetic group). When the cyanobacterial proteins are compared with analogously functioning proteins in other cyanobacteria or in eukaryotes it would seem that their rates of evolution are much less than the rates of evolution of the proteins in eukaryotic algae and higher plants. The results seem very much against the hypothesis of neutral mutation in protein[36]. This is the hypothesis that most evolutionary change in DNA is not due to Darwinian natural selection but to selectively neutral mutations which become passively fixed through the action of random genetic drift. These selectively neutral mutations in DNA result in substitutions of amino acids in proteins which do not cause appreciable changes in protein function. In fact this does not seem to be the case here. It would seem that the role of neutral mutation is small and the amount of change in these cyanobacterial amino acid sequences which has occurred seems to reflect the functional differences between the proteins in the variety of organisms. For example it was seen that the cyanobacterial and red algal cytochrome *f* were particularly close.

It is also possible that the pattern of divergence in cyanobacterial primary structures has been obscured by transfer of genetic information coding for these photosynthetic proteins. There is evidence to suggest that this has occurred between distantly related bacteria[37], but whatever the reason for the sequence comparisons obtained, protein sequence studies have produced a considerable amount of evidence for the hypothesis of the common origin of oxygenic photosynthesis in prokaryotes and eukaryotes. It seems unlikely, however, that molecular methods will enable construction of phylogenetic trees which would indicate the precise manner in which cyanobacteria evolved into chloroplasts or chloroplast-containing eukaryotes.

I thank Dr R. P. Ambler for invaluable advice and assistance

New approach to steroid conversion using activated immobilised microorganisms

THE marked increase in demand for contraceptives and anti-inflammatory agents such as cortisol and prednisolone, combined with a diminishing supply of steroid raw materials may lead to shortages of steroid drugs[1]. Thus it is important to develop new sources for steroids as well as to devise more efficient means for steroid conversions. Here we report a new approach to steroid transformation in which activated immobilised microorganisms are utilised and which represents a promising alternative to conventional microbial transformation processes.

Immobilised microorganisms have attracted increasing interest as catalysts in the past few years[2–4] They have the same operational advantages as those inherent in immobilised enzymes[5], they are reusable, they are well suited for continuous operation in controlled conditions and further, there is no stringent demand for asepsis during opera-

tion. Immobilised microorganisms offer the additional advantage that tedious and costly enzyme isolation is obviated, that the enzyme is usually more stable due to its localisation in its "natural environment", and that there is usually no need for cofactor. Thus, provided competing reactions can be eliminated, immobilised microorganisms are very promising catalysts.

In this communication we consider especially a property unique to immobilised whole-cell catalysts—the possibility of *in situ* activation of the immobilised enzyme activity. The system studied was the important corticosteroid transformation cortisol $\xrightarrow{\Delta^1\text{-dehydrogenase}}$ prednisolone. The reaction was catalysed by polyacrylamide-entrapped *Corynebacterium simplex*.

C. simplex cells were grown in a medium of 0.25% yeast extract; the Δ^1-dehydrogenase activity being induced by addition of cortisol to the culture 12 h before collection by continuous centrifugation at 10,000g. The cells (5 g wet weight) were suspended in 20 ml of ice-cold 0.1 M Tris-HCl buffer, pH 7.5, and mixed with 25 ml of ice-cold aqueous monomer solution containing 7.13 g of acrylamide and 0.38 g of *N,N'*-methylene-*bis*-acrylamide. The mixture was poured into a sandwich-like polymerisation vessel (made of two glass plates 20×20×0.2 cm, spaced 2 mm apart with a piece of latex tubing) and the catalyst potassium persulphate (50 mg) and tetramethylenediamine (100 mg) were added in water (1 ml). Nitrogen gas was bubbled through the suspension and polymerisation started within 2 min. The polyacrylamide gel sheet was fragmented in a blender and the gel granules (average size 0.2 mm) were washed extensively with Tris buffer and then stored at −20 °C at which temperature the preparation was stable for several months.

The 3-ketosteroid-Δ^1-dehydrogenase activity of the immobilised *C. simplex* was assayed conveniently spectrophotometrically (Fig 1), and sole product, prednisolone, was identified by thin-layer chromatography. Approximately 40% of the dehydrogenase activity was retained during the immobilisation procedure (all bacteria added were immobilised and no release of bacteria was observed during incubations). Initial experiments revealed, however, that the activity declined rather rapidly on repeated batchwise conversions of high loads of cortisol and this could only be compensated for to a limited degree by addition of the artificial electron acceptor menadione[6]. Instead the stabilising influence of various nutrients and salts was investigated; the results are given in Table 1. In media

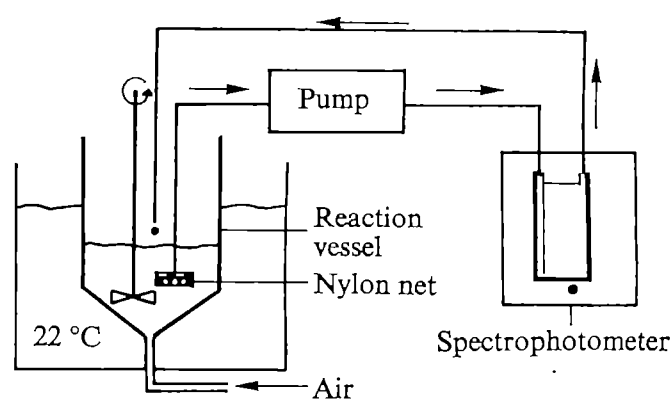
Fig. 1 Assay of Δ^1-dehydrogenase activity. Δ^1-Dehydrogenase activity of immobilised *C. simplex* was determined in air-saturated 1 mM cortisol. The progress of the reaction was monitored at 285 nm by pumping the supernatant through a flow cell ($\Delta\varepsilon = 2,820$ M^{-1} cm^{-1}) The initial transformation rates listed in Table 1 were determined in an assay composition of 0.5 g of gel granules (wet weight)+9.0 ml of 0.05 M Tris-HCl, pH 7.0, plus, 0.5 ml of 20 mM cortisol (methanol).


Fig. 2 Repeated batchwise transformation of cortisol to prednisolone. *C. simplex* gel (2.0 g, wet weight) was suspended in 285 ml of 0 5% peptone, pH 7.0, +15 ml of 20 mM cortisol (methanol). The transformation was carried out in the apparatus depicted in Fig. 1. When 100% conversion to prednisolone was reached (indicated by the location of the points), the gel was washed and again incubated with fresh cortisol-containing medium. The whole experiment lasted 4 d.

consisting of water or buffer the activity decreased, whereas in peptone-containing and glucose-containing media the activity was not only preserved but also increased to several times that of the original activity.

The 0.5% peptone medium and the 0 1% peptone +0.2% glucose medium were selected for further study and an experiment with repeated batchwise transformation was conducted. Both media were approximately equally efficient, and in Fig. 2 the results obtained with the 0.5% peptone medium are depicted. As can be seen, the transformation capacity increased remarkably with each run, thus while in the first batch 100% transformation was obtained after 18 h, the last batch was completed in less than 2 h. The transformation capacity at the end of the experiment was approximately 0.5 g of steroid per d per g of gel (wet weight).

This transformation capacity means that a continuously operating reactor loaded with only 1–2 kg of immobilised *C. simplex* gel would suffice to supply the Swedish demand for 1-dehydrogenated steroids (8 million inhabitants consuming approximately 250 kg of 1-dehydrogenated steroids per year at a value of £5 million). The calculation is based on the assumptions that the catalyst is completely stable, that no decrease in efficiency occurs on scaling up and that the dehydrogenation is the final step in the production of Δ^1-dehydrogenated steroids. Even if these assumptions are too optimistic, the calculation still serves to give some idea of the very modest reactor dimensions needed even for large-scale production of Δ^1-dehydrognated steroids.

Preliminary experiments show that the so-called pseudo-crystallofermentation technique[7] is applicable also to entrapped *C simplex*. Cortisol was thus added in an amount (3.6 g l⁻¹) far exceeding its solubility in the medium and was

Table 1 Activating effect of nutrients on the Δ^1-dehydrogenase activity

Medium	Initial transformation rate (%) after				
	0	2	6	10	16 d
Peptone, 0.5%	100	460	500	650	530
Peptone, 0.1% + Glucose, 0.2%	100	270	230	250	250
Glucose, 0.2%	100	210	170	110	90
K_2HPO_4, 0.1 M, pH = 7.0	100	70	50	60	60
Tris-HCl, 0.05 M, pH = 7.0	100	100	70	70	30
H_2O	100	60	40	40	20

C. simplex gel (0 5 g) was incubated in 9.0 ml of medium as indicated and 0.5 ml of 20 mM cortisol (methanol) was added. The suspension was shaken on a rotary shaker at 25 °C and at ₄8-h intervals the medium was replaced by fresh cortisol-containing medium. At the times indicated the gel was filtered off, washed and assayed for Δ^1-dehydrogenase activity as described in Fig. 1.

completely converted at approximately the same rate as in experiments with dissolved cortisol. The product prednisolone, which precipitated out, could be isolated simply by filtration after the rather dense gel granules had been allowed to settle. This technique allows reduction of media volumes by orders of magnitude and thus also of nutrients.

The reason for the observed activation is not known, it could be microbial growth or protein synthesis Microscopic studies of gel granules revealed that there is at least some increase in the amount of entrapped bacteria. Continuous induction leading to *de novo* synthesis of Δ^1-dehydrogenase in existing cells is also a plausible explanation. Cell lysis, which might enhance substrate/product transport, is, on the other hand, considered a rather unlikely cause of activation, since increased activity was observed only in media containing nutrients (Table 1).

In situ (re)activation procedures similar to that given here should obviously also be applicable to other processes catalysed by immobilised microorganisms, for example, biotransformation of other steroids and antibiotics as well as other compounds.

Polymers for the sustained release of proteins and other macromolecules

Since the first demonstration that silicone rubber[1] could be used as an implantable carrier for sustained delivery of low molecular weight compounds in animal tissues, various drug delivery systems have been developed. But except for the reports of Davis[2,3] and Gimbrone *et al.*[4], there has been little success in the development of slow release agents for large molecular weight compounds. Furthermore, the polymers used in those studies, polyvinylpyrrolidone and polyacrylamide, are often inflammatory in animal tissues and

Table 1 Host response to corneal polymer gel implants

Polymer	No. of tests	Inflammation*		
		None	Mild	Significant
Polyacrylamide, 20%	10	20%	30%	50%
Polyvinylpyrrolidone, 20%	4	0	0	100%
Polyvinylalcohol (unwashed, 1%, 5%, 10%)	20	15%	70%	15%
Polyvinylalcohol (washed, 10%)	6	67%	33%	0
Hydron-S (with and without water in the polymer casting solution)	15	100%	0	0
Ethylene–vinyl acetate copolymer (unwashed)	20	40%	60%	0
Ethylene–vinyl acetate copolymer (washed)	20	100%	0	0

*The criteria were oedema, white cells and neovascularisation as observed through a stereomicroscope. A response was judged to be mild if any one of the three characteristics was detected, and significant if their presence was enough to cause corneal opacity.

usually permit only brief periods of sustained release. We now present a simple method for incorporating various proteins and other macromolecules into non-inflammatory polymers. Sustained release of biochemically active macromolecules has been demonstrated for periods exceeding 100 d.

Sterile polymer casting solutions were made by dissolving polymers in appropriate solvents: Hydron (a polymer of hydroxyethylmethacrylate) in absolute alcohol at 37 °C; ethylene–vinyl acetate copolymer (40% by weight vinyl acetate) in methylene chloride at 37 °C; and polyvinylalcohol by autoclaving in distilled water. Slow release pellets were made by placing a mixture of casting solution and the macromolecule to be released in a conical mould, 2–4 mm in diameter and 1.5 mm deep. Glass moulds were used for the ethylene–vinyl acetate copolymer because the polymer casting solution reacted with plastics causing adhesion. The moulds were dried under a mild vacuum (600 mmHg) overnight causing the solvent to evaporate leaving the macromolecule trapped within the polymer matrix. To retard further release of macromolecules, 'sandwiches' were sometimes made by coating the matrix with pure polymer in casting solution. Coating was achieved by dipping the polymer pellet in a puddle of pure polymer in casting solution and drying. In an alternative method of coating, pure polymer in casting solution was dried in the bottom of a mould, a middle layer of polymer and macromolecule was added and dried, and finally a top layer of pure polymer in casting solution was added and dried. Before use, the dried slow-release pellets were rehydrated by adding a drop of Ringer solution.

To study tissue response to the polymers, sterile polymer pellets (1.5 × 1.5 × 0.5 mm³) were implanted in the eyes of rabbits, by aseptically creating a small pocket in the cornea⁴. Inflammation was judged by stereomicroscopy. The sensitivity of the cornea to inflammatory stimuli as well as its clarity and avascularity make it an excellent site to observe inflammatory characteristics: oedema, white-cell infiltration, and neovascularisation⁵.

Ethylene–vinyl acetate copolymer, exhaustively washed in alcohol, and Hydron caused no inflammation in the cornea (Table 1). Histological sections made 3–4 weeks after implantation showed no foreign cells in the region surrounding the polymers or in other areas of the cornea. In contrast, polyacrylamide and polyvinylpyrrolidone, prepared according to Davis⁶, were significantly inflammatory. Polyacrylamide has been used in our laboratory for several years⁴, and inflammatory responses have been reduced by various washing techniques (R. Arensman and M. Gimbrone, unpublished). Unwashed polyvinylalcohol pellets also caused inflammation. Washing the polymer exhaustively with alcohol greatly reduced, but did not eliminate, the inflammatory response (Table 1).

Polyvinylalcohol, Hydron and ethylene–vinyl acetate copolymer were examined for the ability to release soybean trypsin inhibitor (molecular weight 21,000). The polymer–water ratio in the casting solution of polyvinylalcohol was

important in the determination of release rates. The effects of various polyvinylalcohol concentrations in the casting solution on the rate of release of soybean trypsin inhibitor are summarised in Fig. 1. An increase in the polymer concentration in the casting solution significantly decreased the initial rate at which protein was released. A threshold level was apparently reached at about 10% polyvinylalcohol, because further increases in polymer concentration did little to retard release from the pellet. Water was also added to the Hydron–alcohol–protein casting solution. The greater the water–polymer ratio, the greater was the rate of protein release from the pellet.

Figure 1 illustrates two additional features of these slow release systems: (1) a large percentage of protein was released during the first hour of incubation, that is, 'burst effect'; (2) the rate of release was significantly retarded in polymer 'sandwiches'.

Figure 2a shows the release of soybean trypsin inhibitor from the three polymers. Protein was released from Hydron relatively rapidly, more slowly from polyvinylalcohol, and least rapidly from ethylene–vinyl acetate copolymer. The 'burst' was evident for all three systems.

Fig. 1 Release of soybean trypsin inhibitor from polyvinylalcohol. The percentage of polymer in the casting solution was varied. Protein concentration in all casting solutions was 12 mg ml⁻¹. Release characteristics were studied by incubating polymer pellets in small test tubes with lactated Ringer solution at 37 °C. Periodically, pellets were removed to new tubes containing fresh Ringer solution. Protein release from the pellets was assayed by the Lowry method⁸. Polyvinylalcohol, △, 1.2%; ○, 4.8%; ▲, 6%; ■, 10%; circle and cross, 20%; ●, 10% sandwich.
Fig. 2 a, Release of soybean trypsin inhibitor from Hydron (△), polyvinylalcohol (□) and ethylene–vinyl acetate copolymer 'sandwiches' (○). Protein concentration in all casting solutions was 50 mg ml⁻¹. Polymer concentrations in casting solutions were 12% Hydron, 10% polyvinylalcohol and 10% ethylene–vinyl acetate copolymer. These concentrations minimised initial rates of release from each of the individual polymer systems and still permitted viscosities low enough so that the solutions were easy to work with. b, Release of four proteins from ethylene–vinyl acetate copolymer 'sandwiches'. Protein and polymer concentrations in casting solutions were 50 mg ml⁻¹ and 10%, respectively. Release was studied as described in Fig. 1. △, Lysozyme; ○, soybean trypsin inhibitor; ●, alkaline phosphatase; □, catalase.

Three other proteins, lysozyme (molecular weight 14,400), alkaline phosphatase (molecular weight 88,000), and catalase (molecular weight 250,000) were similarly studied. Their release profiles from ethylene–vinyl acetate copolymer are shown in Fig. 2b. Release rates approach zero-order kinetics over periods of 20–100 d. Using standard assays[7–9], we also found that this polymer released more than 100 ng per day of heparin, and ³H-thymidine-labelled DNA (isolated from mouse SVT2 cells); and in excess of 100 μU per day of insulin for periods exceeding 40 d.

To determine whether the polymers were releasing biochemically active material in vitro, pellets containing 300 μg of lysozyme, soybean trypsin inhibitor, and alkaline phosphatase were placed in 20-ml volumes of Ringer at 37 °C. After 2 d of this incubation, each polymer was washed with 100 ml of Ringer for 5 min and placed on an agar diffusion

slide described before[10–12]. Formation of zones of activity on these slides indicated the release of at least 100 ng per day of biochemically active material. When this cycle was repeated, new zones continued to form for periods exceeding 100 d with ethylene–vinyl acetate copolymer 'sandwiches', and for 14 and 4 d with polyvinylalcohol and Hydron 'sandwiches', respectively. Furthermore, when the specific activity of alkaline phosphatase was tested before and after incorporation into each of the three polymers, more than 80% of the enzyme escaping from the polymers was found to be active.

To determine whether biologically active macromolecules could be released in vivo, ethylene–vinyl acetate copolymer 'sandwiches' containing tumour angiogenesis factor (TAF), a tumour cell extract that induces neovascularisation[13], were tested. Pellets containing TAF were implanted into 20 rabbit corneas and in every case vessels sprouted from the corneal edge and grew towards the polymer. No oedema or white cells were detected. After 40 d, several of the polymers were removed and vessels disappeared within 21 d. When the same polymers were washed in Ringer solution and transplanted to new corneas, vascular responses were again observed, although rates of vessel growth were somewhat slower than with the initial implants. Also, pellets of polyvinylalcohol or ethylene–vinyl acetate copolymer containing TAF consistently produced neovascular responses when implanted on a 10- or 11-d-old chick chorioallantoic membrane. The polymers alone induced no such response.

These studies show that sustained release of proteins and other macromolecules from polymeric vehicles can be achieved over prolonged periods. The mechanism of release of large molecules from these polymers is not entirely clear. The mechanism, at least for ethylene–vinyl acetate copolymer, does not seem to depend on simple diffusion. The same macromolecules which were released so readily from this polymer after incorporation into its matrix, do not diffuse through a film of the pure polymer. Furthermore, when Dextran blue (molecular weight 2,000,000) was incorporated into ethylene–vinyl acetate copolymer, more than 90% was released in 3 d, in contrast to proteins such as alkaline phosphatase (molecular weight 88,000) where 90% release required nearly 100 d. It can be speculated that because this polymer is permeable to water, proteins deep within the polymer matrix may be driven to the surface by osmotic pressure or capillary action.

There are several possible applications. These polymers may be useful in the development of bioassays for various substances, including growth factors, chemotactic compounds and other informational molecules. The ability of ethylene–vinylacetate copolymer in casting solution to bind to plastics may facilitate new approaches for tissue culture experiments. It remains to be seen whether these polymers will eventually be clinically useful for long term delivery of macromolecules such as insulin, heparin or enzymes.

Enhancement in the sweetness of sucrose

THERE IS considerable interest in the relationship between chemical structure, both configurational and conformational and the sweet response[1] particularly in the case of sucrose (1) since, of all the sweetening agents it is the most widely used Hitherto, no derivative of sucrose nor any other carbohydrate has shown sweetness substantially greater than that of sucrose, indeed to the contrary sucrose octa-acetate is very bitter, sucrose monoesters are much less sweet and *galacto*-sucrose (2), a C4 epimer of sucrose, is greatly diminished in sweetness[2]. Nevertheless, one of the objectives in our studies on the chemistry of sucrose has been to modify its structure, by chemical means in order to enhance its natural sweetness and in the process prevent metabolism by inhibiting breakdown by invertase. We have now been greatly encouraged by the surprising discovery that a *galacto*-sucrose derivative, namely 1',4,6,6'-tetrachloro-*galacto*-sucrose (3) is intensely sweet, comparable with saccharin but without an unpleasant after-taste.
Fig. 1 *a*, Sucrose (1; R = R' = R'' = OH) and its 6,6'-dichloro (4; R = R'' = Cl, R' = OH) and 1',6'-dichloro (5; R' = R'' = Cl, R = OH) derivatives; *b*, *galacto*-sucrose (2; R = OH) and its tetrachloro derivative (3; R = Cl)

Lindley, Birch and Khan[3] suggested from studies on methyl ethers of sucrose that the equatorial 4-hydroxyl group of sucrose (1) interacts with the taste buds of the tongue by intermolecular hydrogen bonding and that loss of sweetness in *galacto*-sucrose (2) is due to the axial 4-hydroxyl group being masked by an intramolecular hydrogen bond to the ring oxygen. Whilst our tetrachloro derivative (3) is not in disagreement with the latter observation, the 4-chloro substituent could only act as a hydrogen bond acceptor on the taste bud. Likewise they suggested the importance of the 1'-hydroxyl group of sucrose which is supported by our own observations in that 6,6'-dichloro-sucrose[3] (4) is less sweet than sucrose, implying that in (3) the 1'4-dichloro substituents are enhancing its sweetness. On the other hand 1',6,6'-trichloro[4] and 4,6,6'-trichloro[5] derivatives are more than 10 times sweeter than sucrose but not as intensely sweet as the aforementioned tetrachloro derivative (3). It is highly significant that 1'6'-dichlorosucrose (5) is intensely sweet, like the tetrachloro derivative (3), which

pinpoints the importance of the chloro substituent at the 1'-position on the molecule of sucrose.

If the Shallenberger theory of sugar sweetness[6] is correct, where two electronegative atoms A and B separated by 2.5–4 0 Å initiate the sweet taste by intermolecular hydrogen bonding between A–H and B and similar groups on the receptor site, then it would seem that the 1'-chloro substituent is the proton acceptor B and the 2-hydroxyl on the glucosyl moiety is A–H, the proton donor. The intense sweetness of the chloro compounds 3 and 5 could also be due in part to their greater lipophilic character than sucrose. The subtle interplay of intramolecular bonding in the sucrose molecule has an important role and the introduction of chloro substituents seems to have reinforced the effect. The sucrose derivatives in which a 6-hydroxyl of the fructo-furanosyl unit of sucrose has been replaced by a chloro substituent are resistant to the action of invertase, a β-D-fructofuranosidase (J. Chapman, unpublished results). Hence in the development of alternative sweeteners from sucrose, as for example for application in dietetic food, combining high sweetness with low calorie content, the chloro derivatives are worthy of further evaluation.

Tackling computer myths
Yorick Wilks

The Thinking Computer: Mind Inside Matter. By Bertram Raphael. Pp. xiii + 322. (Freeman: San Francisco and Reading, May 1976.) Cloth £9; paper £4.40.

ARTIFICIAL INTELLIGENCE (AI) is beset by all the difficulties of any immature science. Since so little is agreed among its workers in the way of basic theory and truths, any presentation of it is bound to be inadequate, and that applies especially to any attempt to produce a non-contentious introductory text like the one under review. It is almost inevitable that such a work will be parochial in terms of the research laboratory it comes from, and the areas within the field on which it concentrates. To say this is not to blame the author: in the present state of things in AI it could not be otherwise.

Thus the present book is heavily oriented to the research carried out at the Stanford Research Institute (SRI), its author's home, and is strongest in the areas where SRI is strong: robots, formal approaches to problem solving and vision; and weakest where they are weakest: natural language, high level programming languages, and the sort of speculation about 'knowledge structures' that has been emerging from MIT in the past two years. The book seems to have been written essentially by about 1972, and is, in that sense, out of date. But, once again, it is a criticism of the subject and not the author that being up to date is considered so important in AI. In a mature science, the basics could be absorbed perfectly well from a four-year-old text-book. In so far as abstract problem-solving techniques, resolution theory in theorem proving, and techniques of the same vintage in vision, are fundamental building blocks of the subject (and to some extent it is undeniable that they are), then they are well and clearly presented here.

The book aims to fill the gap between a wholly popular account of AI research and the style of the technical literature; and is intended to lead anyone interested and armed with 'High School' maths to that literature. It does it rather well, and could be a useful book for first-year University courses in computer science or psychology.

Its concessions to laymen are among its best bits. Raphael begins by tackling what he calls "myths about computers": the Arithmetic Myth and the Stupid Computer Myth, namely that computers can do only what they are programmed to do, which is true but highly misleading. While he was at it he should probably have tackled the contrary myths: that computers are socially all-powerful and as clever as we are. The latter is just as likely to be believed by the man in the street at the moment as the "myths" Raphael does tackle. The book's subtitle, too, *Mind Inside Matter*, is peculiarly unfortunate for an author concerned to debunk myths.

Another bonus is the well illustrated chapter on the history of robots, which contains the marvellous revelation (p 253) that "several key figures in contemporary computer history"—Von Neumann, Wiener and Minsky—are all descendants of the Maharal· the fifteenth-century rabbi of Prague who made, and gave life to, a 'golem', an artificial man made from the clay of a river bank. □

Matrix isolation

Matrix Isolation: A Technique for the Study of Reactive Inorganic Species. By Stephen Cradock and A. J. Hinchcliffe. Pp. 144. (Cambridge University: Cambridge, London and New York, October 1975.) £6.20.

Now acknowledged as one of the primary methods of investigating molecules which are short-lived in conventional conditions, matrix isolation has not lacked reviewers, but books about it have been few and relatively specialised. The present authors are to be commended therefore on producing a compact and eminently readable account of matrix isolation which can easily be digested by undergraduate and graduate students unfamiliar with the technique. The formation and nature of a matrix, interactions within that matrix, and the technical aspects of matrix-isolation experiments are treated at a simple, descriptive level, specific examples are discussed in the closing chapters. There is a short subject index and a cameo-sized bibliography that is bound to disappoint anyone with more than passing interest in the subject.

Assuming that the reader is familiar with much basic physics, chemistry and spectroscopy, the authors have aimed to show how matrix-isolation experiments may be accomplished Assuredly, theirs is a reasonable objective, but the result seems to me overburdened with empiricism, and addicted to assertions unsupported either by argument or by apt example. Without a broader appreciation of the purpose and possibilities of the technique, the reader might be excused for wondering whether the technical mountain has not given birth to a chemical mouse. This doubt is not altogether dispelled either by the range or by the treatment of the examples selected. Certain it is that the authors take a healthily critical view of the results of matrix-isolation experiments: whether those results signify much outside their immediate context has to be taken on trust. If the figures would have repaid a greater expenditure of imagination and trouble, the way in which the story is told recalls Mark Twain's character: "there was things which he stretched, but mainly he told the truth" Mainly this is a sound and worthwhile addition to the chemical literature: it might have been more than that.

A. J. Downs

Dr Downs is a Lecturer in the Department of Inorganic Chemistry at the University of Oxford, UK.

• Catecholamine
· transport systems

The Mechanisms of Neuronal and Extraneuronal Transport of Catecholamines. Edited by David M. Paton. Pp. xi+370. (Raven: New York, February, 1976.) $27.50.

THE discovery by Axelrod and his colleagues that radioactively labelled catecholamines are transported into sympathetically innervated tissues has led to a much better understanding of the physiology and pharmacology of adrenergic neurotransmission, and the early work was summarised in 1967 in what is now becoming a classic book *The Uptake and Storage of Noradrenaline in Sympathetic Nerves* by L. L. Iversen. It is particularly welcome, therefore, that we are brought up to date by the book under review. The editor, in an historical introduction, also reminds the reader that possibly the earliest suggestion that circulating adrenaline might be transported into nerve endings was made by J. H. Burn

in 1932 and first shown experimentally in 1943 by Raab.

The book contains 17 chapters contributed by well-known workers in the field and covers the major catecholamine transport systems known, those across the membranes of sympathetic neurones, of synaptic vesicles and of non-neuronal cells in a variety of tissues. It is of fairly specialised interest, but most workers who study catecholamines and other neurotransmitters will want a copy in their library. Unfortunately, there are some inconsistencies in the book between different authors. Several define precisely what is meant by the term 'uptake' and their definition is welcome; but other authors in the book use the term loosely and are less critical. Finally, the title was not a good choice, for only one chapter covers what is generally understood by the word 'mechanism': the way in which the catecholamine molecule passes across a membrane.

A. D. Smith

Dr Smith is a Lecturer in the Department of Pharmacology at the University of Oxford, UK.

Spectroscopy
updated

Spectroscopy. Vol. 1 : Pp. 304. Vol. 2 : Pp. x+362. Vol. 3 : Pp. x+324. (Science Paperbacks.) Edited by B. P. Straughan and S. Walker (Chapman and Hall: London; Halsted · New York, June 1976.) Paper £5.50 each volume; hardback £9 each volume.

THIS set of three volumes consists of a major reform of *Spectroscopy* by S. Walker and H. Straw issued in two volumes in 1961–62. It covers most of non-nuclear spectroscopy with an approach favouring the molecular aspects rather than deep fundamental theory. Each of the nineteen chapters has its individual authorship, although in some places recognisable parts of the earlier work re-appear. There is a modest amount of cross reference, a degree of common style and no serious duplication apart from the deliberate repetition of an appendix containing some more mathematical features in both volumes 2 and 3. The editors have been effective in imposing SI where units are required but they have not had an eagle eye on the associated algebraic forms, many of which lack a factor $(1/4\pi\varepsilon_0)$ to be consistent with SI They also eschew h in favour of the cumbersome $h/2\pi$.

Volume 1 contains· atomic spectroscopy and various forms of spin resonance including quadrupole nuclei and the Mössbauer effect. In this volume,

nuclear magnetic resonance is only allocated 64 pages which seems light for balance and solids are largely omitted. Volume 2 contains the rotation and vibration features and a chapter on group theory which is at a deeper level than is common in such student texts; the chapter on force constants is more appropriate to this scientific level. The chapter on the far infrared provides interesting experimental detail; instrumentation elsewhere is inevitably briefly covered. Volume 3 covers essentially electronic molecular spectroscopy and includes a special chapter on photoelectron spectroscopy and another on astrophysics and astrochemistry.

This replacement is timely and will be widely welcomed by those who found the earlier edition valuable. The books are somewhat lengthy in parts for chemistry or physics undergraduates, but the volumes should be available in the libraries they use. At M Sc level— or possibly undergraduate chemical physics—it would be very suitable; and also as an introduction to research. It can be strongly recommended for these purposes, although it retains a slightly old fashioned approach to quantum theory which restrains the enthusiasm of this reviewer   **D. H. Whiffen**

Professor Whiffen is Head of the Department of Physical Chemistry at the University of Newcastle upon Tyne, UK.

Hydrolysis
equilibria of
metal cations

The Hydrolysis of Cations. By Charles F. Baes, Jr, and Robert E. Mesmer. Pp. xxi+489. (Wiley-Interscience: New York and London, May 1976.) $49.40; £27.66.

THE first three chapters of this book will be useful to anyone who wishes to acquire a good background knowledge before beginning a study of the complicated hydrolysis equilibria of metal cations. Methods of measurement (chiefly potentiometric) and the interpretation and treatment of data are covered systematically and in a clear style. The authors conclude this section of the book (pp69–70) with a slightly philosophical attempt to answer the question: How certain can we be that the scheme of equilibria that "best" fits the data is indeed the correct one? The meaning to be attached to the word "correct" in this question would seem to be open to a lengthy discussion among philosophers of science.

The next fourteen chapters are devoted to accounts of specific cations, covering almost all the appropriate elements in the periodic table. This part of the book fulfils the authors' object of assembling in convenient form a great deal of information, most of which was published during the 25 years up to 1974. It is not claimed that the information on any particular topic is complete, but each section (together with the references—there are about 900 altogether) provides a good starting point for further study. In the last chapter a brave attempt is made at the difficult task of surveying and rationalising the variety of behaviour described earlier in detail.

There is no conventional subject index but there is a single-page alphabetical index of hydrolysing species, a chapter index in the form of a periodic table and a ten-page list of contents. The book should therefore be quite convenient to use, but the casual reader should not overlook the summary of symbols and definitions. These are not always conventional, and they include the rather unexpected definition. $pH = -\log[H^+]$. The standard of production is high—as is the price. It is a book for libraries rather than for the individual buyer.   **J. S. Coe**

Dr Coe is a Senior Lecturer in the Department of Chemistry at King's College, University of London, UK.

Electron donor–acceptor complexes

Catalysis by Electron Donor–Acceptor Complexes: Their General Behaviour and Biological Rôles. By Kenzi Tamaru and Masaru Ichikawa Pp viii+208 (Kodansha: Tokyo; Wiley · New York and London, March 1976.) $23.40; £11.70

IN view of the large number of recent books and reviews dealing with various aspects of electron donor–acceptor (EDA, or charge-transfer) complexes, one must ask whether this book contributes anything new Unfortunately, aside from one chapter, the answer is no.

The central theme of the book is the chemical properties of EDA complexes, including their reactions, catalysis by EDA complexes, and the biological importance of EDA complexes. Chapters 1 (Introduction, 8 pages) and 2 (Formation of EDA Complexes, 44 pages) present a brief general introduction to the subject of EDA complexes Most of this material is covered more clearly and accurately in earlier books and reviews.

Chapter 3 (Homogeneous Catalysis by EDA Complexes, 40 pages) discusses reactions of EDA complexes and catalysis by complexing in solution. This chapter contains numerous inaccurate and confusing statements and is neither complete nor up to date. Again, this subject is covered much more adequately in any one of several recent books and reviews.

Chapter 4 (Heterogeneous Catalysis by EDA Complexes, 66 pages) deals with the subjects of adsorption through EDA complexing and by EDA complexes, and catalysis by solid EDA complexes. This topic, being the main interest of the authors, is covered in much more detail with numerous references to recent work. I found the chapter interesting and relatively free from errors. No comparable review of these subjects is available elsewhere

Chapter 5 (Role of EDA Complexes in Biochemical Reactions, 40 pages) is again neither complete nor up to date and the subject is covered more adequately elsewhere.

A very substantial fraction of Chapter 5 as well as smaller parts of Chapters 2 and 3 are copied almost verbatim from earlier books and reviews. Perhaps this is why, with the exception of Chapter 4, there are few references later than 1968.

In summary, the only very useful part of this book is the chapter dealing with heterogeneous catalysis Only persons actively interested in this area

are likely to consider paying $23.40 for a 66-page review on the subject

Allan K. Colter

Allan K. Colter is Professor of Chemistry at the University of Guelph, Guelph, Ontário, Canada

Vibrational spectroscopy

Vibrational States. By S. Califano. Pp. xii+335. (Wiley–Interscience· London and New York, April 1976.) £16.75; $34.50.

THIS is a textbook on the theory of vibrational spectroscopy for graduate students. It evolved from a lecture course given by the author in the University of Florence, and is restricted to the theoretical treatment of vibrations of isolated molecules.

The book consists of nine chapters, plus two appendices containing group-theoretical character and correlation tables Chapter 1 is a short introduction to infrared and Raman spectroscopy. Chapter 2 presents the classical theory of small molecular vibrations and includes a very clear account of the separation of translational, rotational and vibrational motion (the Eckart or Sayvetz conditions). The quantum theory is given in Chapter 3, it deals with the one-, two- and three-dimensional harmonic oscillator and with the quantum radiation field. Chapter 4 is concerned with the transformation to internal coordinates and the construction of the F and G matrices for the

force constants and the kinetic energy in terms of the internal coordinates Chapters 5 and 6 are devoted to the principles of group theory and its applications to molecular vibrations, and Chapter 7 to selection rules in infrared and Raman spectra. Various potential functions, including the general valence force field and the Urey–Bradley force field, are discussed in Chapter 8 which includes a brief description of Coriolis coupling, centrifugal distortion, and the *ab initio* computation of force constants. The final chapter is concerned with anharmonicity and Fermi resonance.

The author has given us a clear and detailed account of the main topics in the theory of molecular vibrations. There are omissions, including vibronic coupling, internal rotation, circular dichroism, and Raman spectra resulting from the anti-symmetric part of the polarisability tensor; and a few obscurities and minor errors, such as the comparison at the foot of p20 of quantities having different dimensions. SI units are not used, nor are Mulliken's recommendations (*J chem. Phys.*, **23**, 1997, 1955) for the choice of molecule-fixed axes; the coordinate frames on p19 are left-handed and some of the diagrams (such as that showing a plane of symmetry on p103) are not clear. But overall this is a good book that will be a useful addition to the well-known texts by Herzberg and by Wilson, Decius and Cross.   **A. D. Buckingham**

A D. Buckingham has been Professor of Chemistry at the University of Cambridge since 1969.

Environmental dictionary

Dictionary of Environmental Terms. By Alan Gilpin. Pp. 191. (Routledge and Kegan Paul. London and Henley, September 1976.) £3.50.

THIS book is attractively produced, easy to use, and has some very useful features: the list of abbreviations at the beginning (although why does the MW=megawatt come between p.p.m. and its expansion?) and the Appendix carrying the Statement of the Stockholm Conference on the Human Environment (1972). The important criteria in reviewing such a book are: "Does it contain puzzling words that the student/layman is likely to encounter?" and "Are the definitions sound?". The range of words is admirably broad, but there are some omissions, especially of

biological terms. No 'biotic index'. 'sere' or 'ecotype', for instance, and only 'meteorological stability'. On the pollution side 'fanning' of plumes appears, but no 'slug' or 'slick'; and although 'effluent charge' is included 'consent' or 'consent conditions' is not

'Qualitative and quantitative analysis' probably need not have been included, and the long description of Boulding's green stamp plan for creating a market in procreation, although intriguing, is of only marginal importance.

Some of the explanations are too discursive, more appropriate to a gazetteer than a dictionary. In spite of these criticisms, however, this is a helpful book reasonably priced.

Pauline K. Marstrand

Pauline Marstrand is a Senior Fellow in the Science Policy Research Unit, University of Sussex, UK.

obituary

With the death of **Professor J. C. Slater** at the age of 75, America, and indeed the world, has lost one of its most influential and active practitioners of theoretical physics. For over fifty years Slater produced a continuous and substantial flow of research work, most of it concerned with those aspects of matter which depend primarily on the electronic properties of atoms; treating first the properties of individual atoms as revealed by the multiplet structure of their spectra, and later the properties of atoms in molecular combinations and in the solid state

With the advent of wave mechanics he quickly realised that all such properties are determined by the many-electron wave function of the system, and therefore directed his attention to the invention of suitable approximations and mathematical methods for its calculation. In his search for the wave functions, their eigenvalues, and the density of states they imply, he led a numerous band of gifted students many of whom (now somewhat advanced in years) have followed the trail which he blazed and, with more powerful computers and more refined techniques, have achieved even better results Surely no greater tribute can be paid to a scientist than the successful continuation of his work by succeeding generations.

John Clarke Slater was born on December 22, 1900 into an academic family; his father was professor of English at the University of Rochester. John, after taking his bachelor's degree at this university, went on to Harvard as a graduate student to work under the direction of P W Bridgman In 1922 he travelled to Europe and during a stay of a few months in Copenhagen he became part author, with Bohr and Kramers, of a well-known paper on the quantum theory of radiation Although

the conclusions of this paper proved to be incorrect, it was influential for a time, and for a young man of 23 the association with such famous names was a happy augury indeed.

In 1929 Slater published one of his most important papers which dealt with the theory of multiplets in complex spectra. Folowing the work of F. Hund and applying the newly developed wave mechanics he was able to simplify and extend the calculations of the multiplet structure of atoms with many electrons The basic concept in this work was the expression of the total wave function as a determinant of the single electron wave functions including their spin states Such determinants have ever since been known as Slater determinants and have found applications in many fields, for example, chemistry and metal physics

Following the publication of Heisenberg's theory of ferromagnetism and Bloch's famous paper on the quantum mechanics of electrons in crystal lattices, Slater wrote a paper in 1930 entitled *Cohesion in Monovalent Metals* The significance of this paper in Slater's scientific life is that it marks his introduction into what is now known as solid state physics and which was to remain his principal interest for over forty years. As with many other physicists, however, the years of the second world war caused an interruption in Slater's academic research. During these years he was active in organising the Radiation Laboratory at M.I.T and was involved with research concerning the principles of magnetron design For this work he was awarded a Presidential Certificate of Merit

After the war Slater returned to his interests in solid state physics and began a series of calculations aimed at improving the accuracy of wave functions and the energy levels of electrons

in metals. He developed the method introduced by Wigner and Seitz so that it could be applied to states of higher energy and used the resulting eigenvalue spectrum to construct curves of the density of states. Later he introduced the augmented plane wave method which was widely used by his own students and other physicists. This work, carried out mainly in the decade 1950–60, is not to be judged by the accuracy, or inaccuracy, of particular results but by the thrust which it gave to the advance in this sector of the subject.

Slater was a most prolific writer. Besides about one hundred original papers he wrote eleven books, a few in collaboration with N. H. Frank, but mostly alone, and in addition produced many survey articles, including one giving a detailed history of the development of solid-state and molecular theory. A notable feature of Slater's pedagogic writings is the extraordinary complete bibliography which is invariably attached to each book or article. Evidently very little escaped his attention. It seems clear that he wrote with great facility and speed and that he maintained a confidence in his knowledge and understanding of physics throughout his life

Other aspects of Slater's life and character, for example, his administrative ability which enabled him to take over the headship of the physics department of M.I.T. at the early age of 29, and his gifts as a teacher, can be dealt with adequately only by a close colleague, and in an introductory passage to the volume of articles published to commemorate his 65th birthday, Professor Philip Morse pays a warm tribute to Slater with regard to exactly these qualities. Clearly, Slater was a man of quite exceptional stature in many respects.   **H. Jones**
